

TECHNICAL INNOVATION

IN AMERICAN HISTORY

An Encyclopedia of Science and Technology

Rosanne Welch and Peg A. Lamphier, Editors

About the pagination of this eBook

This eBook contains a multi-volume set.

To navigate this eBook by page number, you will need to use the volume number and the page number, separated by a hyphen.

For example, to go to page 5 of volume 1, type "1-5" in the Go box at the bottom of the screen and click "Go."

To go to page 5 of volume 2, type "2-5" ... and so forth.

Technical Innovation in American History

Technical Innovation in American History

An Encyclopedia of Science and Technology

VOLUME ONE: COLONIAL AMERICA TO 1865

Contents

VOLUME 1: COLONIAL AMERICA TO 1865

Introduction, xxi

Chronology, xxvii

Section 1: Colonial America and Enlightenment Science, 1

Overview, 1

American Philosophical Society, 8

Primary Document: Memorial of the American Philosophical Society Favoring an Exploration of the Alaskan Coast (1868), 10

Astronomical Almanacs, 11

Primary Document: Aphorisms from *Poor Richard's Almanack* (1732–1758), 13

Banneker, Benjamin (1731–1806), 13

Primary Document: Letter of Thomas Jefferson to Benjamin Banneker, Expressing Jefferson's Belief That Blacks Had Talents Equal to Other Races (1791), 14

Primary Document: Frontispiece of Benjamin Banneker's *Pennsylvania, Delaware, Maryland and Virginia Almanack and Ephemeris* (1792), 15

Bifocals, 16

Primary Document: Benjamin Franklin's Letter Describing His Invention of Bifocals (1725), 17

Bushnell, David (1740–c. 1824), 17

Primary Document: Engraving of David Bushnell's *American Turtle* (1775), 18

Colden, Jane (1724–1766), 19

Daylight Saving Time, 20

Extension Arm (Long Arm), 21

Fire Safety, 21

Flexible Catheter, 22

Food Production, Native American, 23

Franklin, Benjamin (1706–1790), 25

Primary Document: Letter of Benjamin Franklin Describing His Experiments with Electricity (c. 1750), 26

Franklin Stove, 27

Primary Document: Excerpt from Benjamin Franklin's *An Account of the New Invented Pennsylvanian Fire-Places* (1744), 28

Glass Harmonica (Armonica), 30

Primary Document: Excerpt of Benjamin Franklin's Letter to Father Giambatista Beccaria Describing the Glass Harmonica (1762), 32

Glover, Elizabeth (d. 1643), 32

Godfrey, Thomas (1704–1749), 33

Iron- and Silversmithing, 34

Kentucky Long Rifle, 35

Lightning Rod, 36

Primary Document: Frontispiece and Title Page of Benjamin Franklin’s *Experiments and Observations on Electricity* (1774), 37

Loom, 38

Primary Document: Excerpts from the Diary of Martha Ballard Describing Home Weaving (1787), 39

Lucas, Eliza (1722–1793), 40

Primary Document: Letter of Eliza Lucas to Her Father (1741), 41

Masters, Sybilla (c. 1675–1720), 42

Mather, Cotton (1663–1728), 43

Natural History, 44

Onesimus (fl. 1706–1716), 46

Peale, Charles Willson (1741–1827), 47

Primary Document: Letter of Charles Willson Peale to Thomas Jefferson Regarding New Agricultural Inventions and Innovations (1815), 48

Priestley, Joseph (1733–1804), 51

Rittenhouse, David (1732–1796), 52

Primary Document: Letter of Thomas Jefferson to David Rittenhouse (1778), 53

“Saugus Pot,” 54

Schooner, 55

Smallpox Inoculation, 56

Primary Document: George Washington’s Order for All Soldiers to Receive a Smallpox Inoculation (1778) and Letter of Edward Rowse to Thomas Jefferson Suggesting the Possibility of Vaccines for Other Diseases (1805), 58

Spinning Wheel, 59

Primary Document: An “Address to the Ladies” Urging American Women to Boycott British Goods (1767), 61

Street Lighting, 62

Swim Fins, 62

Three-Wheel Clock, 63

Primary Document: James Ferguson’s Description of Benjamin Franklin’s Three-Wheel Clock (1773), 64

Turtle Submarine, 65

Primary Document: Letter of David Bushnell to Thomas Jefferson Regarding Bushnell’s Experiments with Submarines (1787), 66

Whiton, David Erskine (1825–1904), 67

Winthrop, John (1714–1779), 68

Primary Document: John Winthrop Describes His Observation of the Planet Venus (1761), 69

Section 2: The New Republic and the Market Economy (1780–1820), 71

Overview, 71

Amphibious Steam Vehicle, 79

Primary Document: Image of an Amphibious Steam Vehicle (1834), 81

Apple Parers, 82

Primary Document: Apple Parer Patent Document Image (1836), 83

Babbitt, Sarah “Tabitha” (1779–1853), 84

Ballard, Martha (1735–1812), 84

Banjo Clock, 87

Blackwell, Elizabeth (1821–1910), 87

Primary Document: Excerpts from “Address on the Medical Education of Women” by Elizabeth and Emily Blackwell (1863), 89

Burr Truss Bridge, 91

Canals, 92

Canning Factory, 95

Charting the Gulf Stream, 96

Circular Saw, 97

Coffee Percolator, 98

- Cotton Gin, 99
- Cotton Sewing Thread, 101
- Dental Floss, 102
- Diffraction Grating, 103
- Erie Canal, 104
 - Primary Document: Letter of Robert Fulton to George Washington Urging Him to Support the Construction of Canals (1797), 106
- Evans, Oliver (1755–1819), 107
 - Primary Document: Letters from Oliver Evans to Thomas Jefferson (1804, 1808), 108
- Fire Hydrant, 109
 - Primary Document: Account of the Detroit Fire (1805), 110
- Fitch, John (1743–1798), 111
- Flatboat, 112
- Fulton, Robert (1765–1815), 114
- Gas Tungsten Arc Welding, 115
- Greene, Catharine Littlefield (1755–1814), 116
- High-Pressure Steam Engine, 117
- Interchangeable Parts, 118
- Internal Combustion Engine, 119
- Jefferson, Thomas (1743–1826), 121
- Lewis and Clark Expedition (1804–1806), 123
 - Primary Document: Excerpts from the Journal of the Lewis and Clark Expedition (1805, 1806), 126
- Lobster Trap, 127
- Lowell Mill System, 128
 - Primary Document: Description of the Life of a Mill Girl from the Lowell Offering (1845), 129
- Milling Machine, 130
- Morey, Samuel (1762–1843), 131
- Multitubular Boiler, 132
- National Road, 132
- Odometer, 135
- Patent and Copyright Statutes, 135
- Practical Ocean Navigation, 137
- Report on Manufactures* (1791), 138
- River Steamer, 139
- Rumford Fireplace, 141
- Rush, Benjamin (1746–1813), 142
 - Primary Document: Excerpt from the Medical Writings of Benjamin Rush (1805), 144
- Screw-Cutting Lathe, 145
- Slater, Samuel (1768–1835), 146
- Steam Engine, 148
- Steam Tractor, 149
- Steamboat, 150
 - Primary Document: Newspaper Announcement of Robert Fulton’s Steamboat (1807) and Charles Dickens’s Account of His Ride on an American Steamboat (1842), 153
- Submarine, 154
- Suspension Bridge, 155
- Swivel Chair, 157
- Thompson, Benjamin (Count Rumford) (1753–1814), 158
- Three-Piece Iron Plow, 159
 - Primary Document: Petition to Congress Asking for a Renewal of the Patent on Jethro Wood’s Cast-Iron Plow (1846), 160
- Vapor-Compression Refrigerator, 161
- Waltham-Lowell Textile System, 161
- Wheel Cipher, 162
 - Primary Document: Excerpts from Thomas Jefferson’s Notes on the Wheel Cipher (Undated), 163
- Whitney, Eli (1765–1825), 163
 - Primary Document: Letter of Eli Whitney to His Father Regarding the Ginning of Cotton (1793), 165

Section 3: Antebellum Industrialization and the Civil War (1820–1865), 167

Overview, 167

Adhesive Tape, 174

Agassiz, Louis (1807–1873), 175

Primary Document: Excerpt from the Journal of Louis Agassiz Describing a Trip to the United States (1846), 176

Anesthesia, 178

Ball Bearings and Babbitt Metal, 179

Best Friend Steam Engine, 181

Breast Pump, 182

Brown Truss, 182

Burglar Alarm, 183

Calliope (Steam Organ), 183

Cannon, Double-Barrel, 185

Primary Document: Excerpt from the Memoirs of Former Confederate General Edward Porter Alexander on “Artillery Hell” at Antietam (1907), 186

Civil War Medicine (1861–1865), 186

Primary Document: Report of Medical Director Robert Murray on Union Casualties Suffered at the Battle of Shiloh (1862), 188

Civil War Nursing, 190

Primary Document: Clara Barton’s Poem “The Women Who Went to the Field” (1892), 192

Clipper Ship, 194

Primary Document: Excerpts from the Journal of Alexander Van Valen Describing His Journey to California via Clipper Ship (1849), 196

Clothespin, 196

Coal-Mining Technologies, 197

Coil Magnet/Electromagnet, 199

Colgate, William (1783–1857), 200

Colored Female Free Produce Society, 201

Colt, Samuel (1814–1862), 202

Colt Revolver, 203

Columbiad Cannon, 204

Combine Harvester, 205

Compact Iron Stove, 207

Conestoga Wagon, 208

Primary Document: Excerpt from John G. Abbott’s Recollections of Traveling to California by Wagon Train (1852), 210

Corn Sheller, 211

Corset, 211

Coston, Martha (1826–1904), 213

Cowboy Hat (Stetson), 213

Crumpler, Rebecca (1831–1895), 214

Cylinder Pin Tumbler Lock, 216

Dahlgren Gun, 216

Deere, John (1804–1886) and Deere and Company, 217

Dental Chair, 219

Detachable Collar, 219

Dix, Dorothea (1802–1887), 220

Dustpan, 221

Eggbeater, 222

Electric Doorbell, 223

Electric Stove, 223

Electric Street Railway, 223

Elevator Safety Brake, 224

Equatorial Sextant, 225

Field, Cyrus West (1819–1892), 226

Fire Alarm Call Box, 227

Floating Dry Dock (1849), 228

Primary Document: Excerpt from Abraham Lincoln’s Patent Application for the Floating Dry Dock (1849), 229

Gas Well, 230

Gold-Mining Technologies, 231

Goodyear, Charles (1800–1860), 232

- Grain Elevator, 233
- Gridiron for Cooking, 234
- Hand-Cranked Ice Cream Maker, 234
- Health Reform, 235
- Henry, Joseph (1797–1878), 237
- Hoop Skirt, 238
- Horse-Drawn Streetcar, 239
 - Primary Document: Image of a Horse-Drawn Streetcar (c. 1920), 240
- Hospital Transport Service, Women’s Department, 240
- Howe, Elias (1819–1867), 241
- Howe Truss, 242
- Interchangeable Gun Parts, 243
- Inverted Microscope, 244
- Jervis, John B. (1795–1885), 245
- Land Mines, 245
- Long, Crawford Williamson (1815–1878), 246
- Machine/Gatling Gun, 247
- Mason Jar, 249
- Maynard, Edward (1813–1891), 249
- Maynard Carbine, 250
- McCormick, Cyrus (1809–1884), 252
 - Primary Document: Letter of Robert E. Lee to Cyrus McCormick Regarding the Curriculum at Washington College (1865), 253
- Mechanical Reaper, 254
- Merrick, Solymon (1806–1852), 255
- Military Technology (Civil War), 255
- Mitchell, Maria (1818–1889), 258
- Morse, Samuel F. B. (1791–1872), 260
- Morse Code, 261
- National Academy of Sciences (NAS), 262
- Nightingale Plan, 263
- North, Simeon (1765–1852), 264
- Omnibus System, 265
- Papermaking Machine, 266
- Pencil Eraser, 267
- Pepper (and Salt) Shaker, 267
- Perkins, Jacob (1766–1849), 267
- Platform Scale, 268
- Polished Steel Plow, 269
- Printing, 269
- Printing Telegraph, 271
- Pullman, George Mortimer (1831–1897), 273
- Railroad T-Rail and Tie, 273
- Railroads, 274
 - Primary Document: Pacific Railway Act (1862), 276
- Ratchet Wrench, 279
- Relay, 280
- Repeating Rifle, 280
- Roller Skates, 282
- Rotary Hook (for Sewing Machines), 283
- Rucker Ambulance, 283
- Safety Pin, 284
- Sewing Machine, Automated, 284
- Sewing Pattern, 286
- Solar Compass, 287
- Spar Torpedo, 288
- Steam Locomotive, 288
- Steam Shovel, 291
- Stevens, Robert Livingston (1787–1856), 292
- Strauss, Levi (1829–1902), 294
- Telegraph, 294
 - Primary Document: Act Authorizing Construction of a Transcontinental Telegraph (1855), 297
- Ten-Hour Movement, 297
 - Primary Document: Excerpt from the Preamble and Constitution of the Lowell Female Labor Reform Association (1846), 298
- Toothpaste, 299

Torpedo, 301
 Transatlantic Cable, 302
 Transverse Shuttle, 303
 Twine Knotter, 304
 Twist Drill, 304
 United States Capitol Building, Construction of, 304
 U.S. Sanitary Commission (USSC), 306

Vulcanization, 307
 Walker, Mary (1832–1919), 308
 Western Union Telegraph Company, 310
 Zipper, 311
Bibliography: Colonial America to 1865, 313
Index, 317

VOLUME 2: RECONSTRUCTION THROUGH WORLD WAR II

Section 1: The Rise of Industrialism, Reconstruction, and the Gilded Age (1866–1900), 1

Overview, 1

Abbe, Cleveland (1838–1916), 7

AC Generator and Transformer, 9

Primary Document: American Institute of
 Electrical Engineers (AIEE) Member
 Biography for William Stanley (1934), 10

AC Induction Motor, 10

Primary Document: Nikola Tesla's Patent for an
 AC Induction Motor (1896), 11

Adding Machine with Keys, 14

Amalgamated Clothing Workers of America
 (ACWA), 14

American Telephone and Telegraph Company
 (AT&T), 16

Asphalt, 17

Aspirin, 18

Barbed Wire, 19

Primary Document: Excerpts from an Article on
 Joseph F. Glidden and the Barb-Wire
 Industry (1884), 21

Batteries, 23

Bee Smoker, 24

Primary Document: Excerpt on the Use of a Bee
 Smoker from Moses Quinby's *Mysteries of
 Bee-Keeping Explained* (1853), 24

Bell, Alexander Graham (1847–1922), 26

Primary Document: Letter of Alexander Graham
 Bell to His Parents Describing His Idea for
 the Telephone (1874), 27

Berliner, Emile (1851–1929), 29

Brooklyn Bridge, 30

Camera, 31

Can Opener, 33

Carnegie, Andrew (1836–1919), 34

Carnegie Steel Mill, 35

Primary Document: Correspondence of Andrew
 Carnegie and Henry Clay Frick Regarding
 the Homestead Strike (1892), 37

Carpet Sweeper, 38

Carver, George Washington (1861–1943), 38

Primary Document: George Washington Carver
 Addresses Congress (1921), 41

Cash Register, 42

Celluloid, 42

Coca-Cola, 43

Cotton Candy Machine, 45

Crayons, 45

Curling Iron, 47

Diner (Horse-Drawn), 47

Dishwashing Machine, 48

Dow Chemical Company, 49

- du Pont, Pierre (1870–1954), 50
- DuPont Company, 52
- Duprey, Ana Roqué de (1853–1933), 54
- Duryea, Charles (1861–1938) and Frank (1869–1967), 54
- Earmuffs, 55
- Eastman, George (1854–1932), 56
- Eastman Kodak Company, 56
- Edison, Thomas (1847–1931), 57
- Electric Iron, 59
- Electric Lightbulb, 60
- Electricity, War of the Currents, 61
- Electrification, Urban, 63
- Escalator, 65
- Ferris Wheel, 66
 - Primary Document: Telegrams between Luther Rice and George Ferris Following the Successful Test of the Ferris Wheel (1893), 68
- Folding Cabinet Bed, 68
 - Primary Document: Patent for Folding Cabinet Bed (1885), 69
- Food Preservation, 70
- Fountain Pen, 71
- Frasch Process, 72
- Gas Transmission, 73
- General Electric, 74
- Goodrich, B. F. (1841–1888), 75
- Goodyear, Charles, Jr. (1833–1896), 76
- Hallidie, Andrew Smith (1836–1900), 76
- Harvard Computers, 77
 - Primary Document: Undated Photo of the Harvard Computers, 79
- Haynes, Elwood (1857–1925), 79
- Heyl, Henry (1842–1919), 80
- Ice Cream Soda, 81
- Inman, George (1895–1972), 82
- Iron Ship with Revolving Turret, 83
- Ironing Board, 83
- Jeans, 84
- Jockstrap, 86
- Jones, Amanda T. (1835–1914), 86
 - Primary Document: “The Soldier’s Mother” by Amanda T. Jones (1867), 87
- Kellogg, William Keith (1860–1951), 88
- Kelly, William (1811–1888), 89
- Kier, Samuel (1813–1874), 90
- Kinematoscope, 91
- Knight, Margaret (1838–1914), 91
- Lady Stitchers’ Union, 92
- Lawn Mower, Reel-Type, 93
- Lennox, David (1855–1947), 93
- Linotype Machine, 94
- Margarine, 95
- Matchbook Matches, 96
- Matzeliger, Jan Ernst (1852–1889), 96
- Maxim, Hudson (1853–1927), 97
- Metal Detector, 97
- Metal Electrode Weld, 98
- Metal Windmill, 99
- Military Technology (Post–Civil War through World War I), 100
- Motion Picture Camera, 102
- National Consumers League, 104
- National Institutes of Health (NIH), 105
- Niagara Falls Power Plant, 106
 - Primary Document: Excerpt from Nikola Tesla’s Commemoration Address for the Niagara Falls Power Plant (1897), 108

Office Technology (Pre–World War II), 112

Paper Bag, 114

Paper Clip, 114

Phonograph, 115

Primary Document: Roll Call of Companies at
the Phonograph Convention in Chicago
(1890), 119

Photographic Film, 120

Pipe Wrench, 121

Player Piano, 121

Portland Cement Mortar, 122

Punch Card Tabulator, 123

Quadruplex Telegraph, 124

Railroad Refrigerator Car, 125

Railroad Sleeping Car and Pullman Car, 126

Railroad Switch Systems, 127

Richards, Ellen Swallow (1842–1911), 128

Roebing, Emily (1843–1903), 129

Primary Document: Photograph of the Promenade
on the Brooklyn Bridge (1899), 131

Roebing, John (1806–1869), 131

Roll Film, 133

Roller Coaster, 133

Rotary Washing Machine, 134

Rowing Machine, 135

Saccharine, 135

Silo, 137

Skyscraper, 138

Soda Fountain, 140

Spork, 141

Steel Arched Bridge, 142

Stethoscope, Binaural, 143

Stockyards, 144

Primary Document: Photograph of Chicago’s
Union Stock Yards (1907), 145

Tape Measure, 146

Taylor, Frederick (1856–1915), 146

Tesla, Nikola (1856–1943), 147

Ticker Tape, 149

Tom Thumb Locomotive, 150

Primary Document: John Latrobe’s Description
of the *Tom Thumb* Locomotive (1830), 150

Track-Type Tractor, 152

Transcontinental Railroad, 153

Twine Self-Binding Harvester, 155

Typewriter and QWERTY, 155

Velocipede, 156

Vending Machine, 157

Vibrator, 158

Water Heater, 159

Westinghouse Air Brake, 160

World’s Fairs, 161

Wright, Wilbur (1867–1912) and Orville
(1871–1948), 164

Primary Document: Entry from Orville Wright’s
Diary of December 17, 1903, 166

Yerkes Observatory, 166

Section 2: The Progressive Era and the Roaring Twenties (1900–1929), 169

Overview, 169

Aerosol Spray Can, 176

Airplane, 176

Anderson, Mary (1866–1953), 179

Assembly Line, 179

Primary Document: Excerpt from Henry Ford’s
“The First Assembly Line” (1913), 181

Automobile Technologies (Pre–World War II), 181

Bakelite, 183

Band-Aid, 185

Bell Telephone Laboratories, 185

- Binney & Smith Inc., 186

Introduction

Technological Innovation in American History: An Encyclopedia of Science and Technology comprises three chronologically arranged volumes. Each of the three volumes is divided into three chronological sections, and each section begins with an introductory essay followed by a mix of entries and primary document excerpts that cover topics and people characteristic of the period. Together, the three volumes contain over 700 entries and 91 primary document selections.

For many entries, it was difficult to know whether the inventor/innovator or the invention/innovation should take the lead. The editors made a decision based on the relative significance of the invention/innovation as compared to the multiplicity of the inventor/innovator's work. A person who invented a number of items received an entry in his or her name, while a person who invented one significant object lost out to the object. Some of the most majorly productive American inventors/innovators, such as Benjamin Franklin, Thomas Edison, and Steve Jobs, have both biographical entries and entries on their numerous contributions to American science and technology.

Also, some obscure inventions/innovations and persons are included in the encyclopedia so as to widen its scope and include persons not generally included in such a collection. The editors endeavored to be inclusive so as to introduce readers to a wider spectrum of the national experience. Some might dismiss this inclusiveness as weak-minded political correctness, but we argue that "correctness" is not a vice. Rather, it is a significant American and human value and one worth honoring.

In most cases, the entry writers and editors chose traditional sources for an entry's Further Reading

bibliography and the general bibliographies for each volume, not to privilege print sources but because most readers need little help finding electronic sources. Nonetheless, the 21st century has given professional historians and writers an invaluable ocean of information worth sharing with students and general readers who are the core audience of this work.

The "See also" cross-references at the end of each entry are not meant to be complete. Rather, they function as a guide to lead the reader to other entries that might be of interest. We say "might" because no editor, no matter how skilled, can foresee how a reader will use an entry or what material in an entry will prove the most useful. Cross-referenced entries at the start of a "See also" reference are for other entries in the same volume and section being consulted; cross-referenced entries in other areas of the encyclopedia then follow and are marked with the volume and section information to make finding them easier and more efficient.

ORGANIZATION

Technological Innovation in American History is divided chronologically into the following sections.

Volume 1: Colonial America to 1865

Section 1: Colonial America and Enlightenment Science

Covering inventors and innovations from the 17th century to about 1780, this section explores the earliest days of American science and technology. Colonial and Revolutionary Americans did not have the educational or institutional infrastructure in place to

create a notable culture of innovation, particularly when compared to most European countries. The realities of colonial life meant that Euro-Americans worried more about basic survival than they did progress in science, or what they called “natural philosophy.” Indigenous people had long-standing traditions in medical science, agricultural technologies, and metalworking, but by and large, colonial Americans dismissed these technologies as “primitive” and beneath notice.

Benjamin Franklin was colonial America’s most prolific and significant scientist and inventor. Franklin engaged in groundbreaking studies in electricity that led to his invention of the lightning rod and a static-electricity generator. He also invented swim fins, bifocals, a musical instrument called the glass harmonica, an improved urinary catheter, and the Franklin stove. In the true spirit of collaboration and scientific openness, Franklin never patented his inventions, believing as he did that innovation could only grow if shared. Franklin also cofounded the American Philosophical Society in 1743. That institution continues to promote American scientific research.

Revolutionary-era astronomer David Rittenhouse built the nation’s first significant telescopes and a number of navigational mechanisms.

Section 2: The New Republic and the Market Economy (1780–1820)

After the conclusion of the American Revolution in 1783, the United States began a process of gradual westward expansion. This expansion both encouraged and produced a number of scientific discoveries and technological innovations. When not engaged in politics, Thomas Jefferson was an enthusiastic proponent of American science and an inventor himself. Among his inventions were an improved swivel chair, a dumbwaiter for wine, the revolving bookcase, and a wheel cipher for sending coded messages that he never built and that was reinvented by the American military in the early 20th century.

Jefferson also promoted the now famous Lewis and Clark Expedition, which explored the North American west from 1804 to 1806. Although the expedition’s primary mission was to discover the

“Northwest Passage,” a waterway leading from the Missouri River to the Pacific Ocean, the explorers were also tasked with creating a record of western wildlife and plant life. Though the Northwest Passage proved nonexistent, the 5,000 pages of journals authored by Meriwether Lewis and William Clark continue to provide scholars with a wealth of information about the flora, fauna, and indigenous peoples of the intermountain west.

Improvements in steam power led to a wealth of steam-powered mechanisms, from steamboats to steam tractors. Steam power provided American farmers and industrialists with an affordable and relatively rapid way to move goods about the country.

Canal building, culminating in the massive Erie Canal project in New York, pushed trans-Appalachian expansion. Begun in 1817 and completed in 1825, the Erie Canal crossed 350 miles between the Hudson River and the Great Lakes. The canal proved an almost immediate economic success, because in providing a link between the East Coast and the Great Lakes, it opened markets in northern Ohio, Illinois, and Indiana.

Section 3: Antebellum Industrialization and the Civil War (1820–1865)

American technological innovation exploded during the decades before the American Civil War (1861–1865), so much so that the era is often referred to as the Industrial Revolution.

Railroads proved an even greater boon to the American economy than did canals. Improvements in steel production and steam technology allowed a plethora of railroad companies to spring up in every state, fundamentally changing the way people and goods moved through the country. The telegraph proved a significant change in the way Americans communicated, allowing near-instantaneous communication over long distances for the first time in world history.

In 1847, astronomer Maria Mitchell gained worldwide fame when she became the first person to discover a comet with a telescope. A year later, she became the first woman elected to the American Academy of Arts and Sciences.

Volume 2: Reconstruction through World War II

Section 1: The Rise of Industrialism, Reconstruction, and the Gilded Age (1866–1900)

In many ways, the four decades after the Civil War expanded upon the technological innovations of the antebellum period. Railroads continued to expand upon the transportation revolution, culminating in the completion of the Transcontinental Railroad. The 1862 Pacific Railroad Act allowed the Union Pacific and Central Pacific Railroad companies to build two rail lines, one stretching east from Sacramento, California, and the other west from Omaha, Nebraska. The companies' rail lines met in Promontory, Utah, in May 1869 and ushered in decades of western migration.

Inventors like Thomas Edison and Alexander Graham Bell changed the American landscape even further. Edison pioneered the domestic and commercial use of electrical light and power in the 1870s and 1880s. His support of direct current (DC) distribution set off the “War of the Currents” when George Westinghouse and Nikola Tesla both championed alternating current (AC).

The Gilded Age was also the age of applied science or science applied to technology for economic gain. Thomas Edison personified this branch of American science, founding a multitude of companies based on his inventions, which made him one of America's richest inventors.

While early 20th-century science and technological innovations were numerous, perhaps the most important event of the age happened at Kitty Hawk, North Carolina, in 1903. Orville and Wilbur Wright, brothers and partners in a bicycle shop, accomplished the first heavier-than-air, controlled, power-driven human flight. Few people besides their sister, Katherine, who operated the shop when they were away experimenting, understood the importance of the Wright brothers' achievement. They would usher in a century wherein flight became central to the human experience.

Section 2: The Progressive Era and the Roaring Twenties (1900–1929)

While women had always played a role in American science and technology, the 20th century saw immense

improvement in women's education and increased opportunities for meaningful work outside the home. Alice Bryant invented a variety of surgical instruments; Lizzie Dickelman innovated agricultural mechanisms, including a chicken brooder and a grain bin; and Mary Phelps Jacob, also known as Caresse Crosby, invented the modern brassiere. Born in Germany, Amalie Emmy Noether moved to the United States when Jewish professors were fired en masse in her native land. In her new country, she made so many contributions to abstract algebra and theoretical physics that Albert Einstein called her the most important woman in the history of mathematics. Meanwhile, astronomer Annie Jump Cannon invented modern star classification.

Section 3: The Great Depression and World War II (1930–1945)

The worldwide depression of the 1930s, known as the Great Depression, hit the United States particularly hard. By 1932, one-quarter of all working Americans, 12 million people, were unemployed. The economic hardships created an antiscience climate and a weakening of the federal government's support of science. Research funding dried up, as did university programs, because newly minted doctors of philosophy had little or no chance of finding jobs. Moreover, many people pointed out that science had failed to predict the economic disaster and that applied technologies might have contributed to the depression. The environmental disaster that was the Dust Bowl could be laid, in part, at the foot of the tractors and plows that had allowed the overfarming of the Midwest.

The American entry into World War II in late 1941 effectively ended (though perhaps only temporarily) the nation's antiscience-and-technology phase. In many ways, the World War became a contest between two technological systems: the European system of making small numbers of highly engineered products versus the American system of making large amounts of replaceable goods. The United States effectively outmanufactured its enemies, building vast numbers of tanks, airplanes, ships, and other military goods that would win the wars in Europe and the Pacific.

The United States also benefited from the Nazi “brain drain,” when German-born scientists fled their

country for America. Most notable among these scientists were Einstein and Noether, but Enrico Fermi and Niels Bohr also came to the United States. During the war, Niels Bohr, along with Robert Oppenheimer and many others, worked at the Manhattan Project to develop the first nuclear bomb.

Volume 3: The Cold War to the Present

Section 1: The Cold War (1946–1979)

The scientific and technological success of World War II convinced the American people of the efficacy of state-funded science and technology research. Much of this research was aimed at Cold War military technologies, though the three decades after World War II also saw great strides in medicine, meteorology, ecology, and computer science.

Rachel Carson published her groundbreaking book *Silent Spring* in 1962, which described the adverse effect of chemical pesticides on the environment. The chemical industry rushed to discredit Carson as a hysterical and ill-informed woman. Today she is considered one of the founders of the American environmental movement.

In 1969, the National Aeronautics and Space Administration (NASA) launched Apollo 11, which became the first space mission to land a person on the moon. The nation rejoiced both in the accomplishment of the endeavor and in the fact that the United States had won the Space Race with Russia. To date, the United States is the only country to have landed human beings on the lunar surface. Though all the Apollo astronauts were men, a group of female pilots took and passed all the astronaut tests. Later dubbed the Mercury 13, these women were never an official part of NASA's astronaut-training program.

In 1972, Atari released the first video game, *Pong*, unleashing a video game industry that would come to dominate the home entertainment markets in years to come.

Section 2: The Post–Cold War Era (1980–1999)

The 1980s saw a revolution in computer technology spurred on by improvements in chip technology. Previous events, such as Jack Kilby and Robert Noyce

developing the first integrated chip and the launch of the IBM 360 in 1964, revolutionized computing by differentiating between architecture and computing materials. Smaller, more affordable home computers followed in the next decades, including the HP 9100A (1968), the first desktop computer; the MITS Altair 8800 (1975), the first hobby computer; and the Apple I (1976), Apple's first single-board computer. These advances soon created a world where computers became as commonplace as televisions and microwave ovens.

The 1980s also saw NASA's Space Shuttle program expand our knowledge of astronomy, space physics, and many other sciences. Sally Ride became the first American woman in space in 1983.

Section 3: The New Millennium (2000–Present)

While electronic innovations, from the iPod to the e-book and e-readers, characterize the last 20 years of American innovation, many Americans profess to be antiscience and against funding for public science. For example, NASA's Space Shuttle program ceased in 2011, ending a decades-long American space program. The shuttles had helped build the International Space Station, carried the Hubble Telescope to low-earth orbit, and serviced space stations, space laboratories, and satellites.

In 2017, more than 600 American cities hosted a March for Science to protest the politicization of scientific research and evidence-based public policies. At the same time, public scientists like astrophysicist Neil deGrasse Tyson and Bill Nye have attained rock star–like status in popular culture.

While a vocal minority of Americans are hostile to science, the vast majority of Americans embrace the contributions that science has made to their lives. Innovations in health care like the birth control patch; increasingly sustainable automobiles, including hybrid vehicles; and Internet shopping supported by PayPal are considered normal parts of American life.

The Human Genome Project, launched in 1990, was completed in 2000. The project identified all the genes in the human genome (not just the genes of one human) and was funded by the National Institutes of Health (NIH).

The early decades of the 21st century may prove particularly fertile ground for female scientists and inventors as schools and colleges work to encourage young women in science, technology, engineering, and mathematics (STEM) education. Women like

astronaut Mae Jemison, astronomer Jill Tarter, and animal scientist Temple Grandin have provided girls and young women with role models unavailable to earlier generations.

Chronology

- 1638:** Elizabeth Glover establishes colonial America's first printing press.
- 1641:** The first North American patent is issued to Samuel Winslow for salt processing.
- 1717:** Eleven-year-old Benjamin Franklin invents swim fins, beginning a long and varied career as an inventor and innovator.
- 1719:** Gunsmiths Robert Baker and Martin Meylin produce early Kentucky long rifles.
- 1721:** Cotton Mather promotes smallpox inoculations in Boston. During the American Revolution, the Continental Army's willingness to inoculate soldiers creates an advantage for the army against the British.
- 1742:** Benjamin Franklin's circulating stove, known as the Franklin stove, improves home heating.
- 1743:** The American Philosophical Society is founded in Philadelphia; the Society is still in operation today.
- 1749:** The lightning rod is invented by Benjamin Franklin to protect people and buildings.
- 1753–1758:** Jane Colden categorizes over 300 types of plants in the Hudson River Valley, making her America's first great yet largely unrecognized botanist.
- 1776:** Thomas Jefferson introduces the first swivel or revolving chair, eventually changing the way bored office workers use their time.
- 1782:** Rectangular, flat-bottomed boats, or flatboats, are introduced to navigate inland waterways for the purpose of affordably moving agricultural goods to market.
- 1787:** Oliver Evans invents the automatic flour mill, the first fully automated production system, which in turn makes flour more affordable.
- 1793:** Catharine Littlefield Greene and Eli Whitney invent the cotton gin, ushering in the age of King Cotton that would lead to the Civil War. Greene would be largely forgotten to American history until the 21st century.
- 1795:** Thomas Jefferson invents the wheel cipher for sending coded messages; variations on the wheel are used as late as World War II.
- 1801:** The first suspension bridge is built in Uniontown, Pennsylvania.
- 1801:** Philadelphia installs the nation's first fire hydrant. Before the widespread use of urban water systems and fire hydrants, large portions of cities regularly burned down.
- 1804:** The Burr truss is introduced in covered bridge technology.
- 1804–1806:** The Lewis and Clark Expedition, guided in part by Sacagawea, explores the American West. The expedition fails to find the Northwest Passage, a legendary waterway linking the Pacific and Atlantic oceans, but it does succeed as an ethnographical and biological survey team.
- 1805:** Oliver Evans invents a steam-powered amphibious vehicle, an early attempt at a submarine.
- 1806:** The coffee percolator revolutionizes coffee brewing; Americans gradually switch from tea to coffee consumption.
- 1807:** Robert Fulton builds the first American steamboat, and the Age of Steam begins.
- 1808:** The lobster trap allows for the capture of multiple lobsters in one trap.
- 1812:** A smoothbore, large-caliber Columbiad Cannon improves American seacoast defense.

- Columbiads prove so effective, they are used extensively during the Civil War.
- 1813:** Tabitha Babbitt invents the circular saw for sawmill use.
- 1817:** Construction begins on the Erie Canal. Often described as “the Eighth Wonder of the World,” the canal’s great scale inspired decades of American canal building, culminating in the massive Panama Canal.
- 1821:** The Lowell mill system is pioneered, turning thousands of young women into America’s early factory workers.
- 1827:** The Baltimore and Ohio Railroad becomes the first American railroad company. American railways will push westward expansion, industrialization, urbanization, and immigration.
- 1833:** The lockstitch sewing machine, forerunner to all modern sewing machines, is invented.
- 1834:** The combine harvester is introduced by Hiram Moore. It combines the functions of reaping, threshing, and winnowing grain crops in one machine.
- 1834 and 1836:** Female mill workers at Lowell, Massachusetts, organize the nation’s first significant worker’s strike against conditions created by the Industrial Revolution.
- 1836:** Samuel Morse develops Morse code for telegraph communication, making almost instantaneous communication possible.
- 1839:** George Pullman’s railroad sleeping cars revolutionize transcontinental travel; Charles Goodyear patents vulcanized rubber.
- 1847:** Maria Mitchell becomes the first American astronomer who uses a telescope to discover a comet. Mitchell becomes the first American female astronomy professor.
- 1848:** The pin tumbler lock is invented by Linus Yale Sr.
- 1849:** Abraham Lincoln patents a floating dry dock.
- 1851:** Elias Howe patents the zipper, changing clothing design forever.
- 1853:** The spring clothespin is patented.
- 1856:** The hand-cranked eggbeater is introduced to American cookery. Food made with whipped eggs, or meringue, explodes in popularity.
- 1857:** Mass-produced, rolled toilet paper is developed by Joseph Gayetty.
- 1858:** The pencil eraser, screw-top pepper shaker, twine knotter, dustpan, and mason jar are patented.
- 1859:** The first moving staircase, known as the escalator, is invented.
- 1860:** Ellen Demorest markets the first paper sewing patterns. Combined with home sewing machines, the patterns inspire an explosion of home-based sewing.
- 1861:** The Kinetoscope, postcard, and hand-cranked machine gun are patented.
- 1861–1865:** Thousands of American women volunteer as nurses during the Civil War and professionalize nursing.
- 1863:** The National Academy of Sciences is founded.
- 1864:** Rebecca Crumpler graduates from medical school, becoming the nation’s first black female physician. She pioneers health care for women and children.
- 1865:** John Stetson invents the cowboy hat during a hunting trip.
- 1866:** The wall-mounted urinal is introduced to public bathrooms.
- 1867:** The steam-powered motorcycle, or Roper Steam Velocipede, is invented, along with paper clips, barbed wire, ticker tape, water-tube boilers, and the railroad refrigerator car.
- 1869:** The steam-powered vibrator is invented. The Transcontinental Railroad is completed with the driving of the “Last Spike” in the Utah Territory.
- 1870:** Famed beekeeper Moses Quinby invents the first bee smoker. The can opener, feather duster, and sandblaster are also invented.
- 1873:** Earmuffs are invented by Chester Greenwood to solve his cold ear problem. No one knows why he didn’t just put on a hat.
- 1874:** The spork, ice cream soda, jockstrap, and QWERTY keyboard design are invented.
- 1877:** Thomas Edison invents the phonograph at his Menlo Park, New Jersey, facility.
- 1879:** James Ritty invents the “Incorruptible Cashier,” or cash register.

- 1880:** Amanda Jones invents the oil burner for home heating.
- 1881:** The electric chair is invented. The first execution takes place nine years later. The electric iron and metal detector are also invented.
- 1883:** The Brooklyn Bridge is completed with Emily Roebling as architect, a job she took over from the original architect, Washington Roebling.
- 1884:** The first “skyscraper” is built in Chicago.
- 1885:** George Eastman introduces rolled photographic film.
- 1888:** The AC induction electric motor is patented, as are the ballpoint pen and Salisbury steak.
- 1886:** Josephine Cochran invents the first working mechanical dishwasher. In spite of this invention, people continue to leave their dishes in the sink.
- 1887:** The National Institutes of Health (NIH) is founded.
- 1890:** The tabulating machine, shredded wheat, smoke detector, and stop sign all receive patents.
- 1891:** George Ferris builds the first Ferris wheel for Chicago World’s Fair. The wheel is meant to be the centerpiece of the fair and more impressive than the Eiffel Tower, which had been the great innovation of the previous World’s Fair in Paris.
- 1892:** Sarah Boone patents the ironing board, and Frank Hall invents the Braille typewriter.
- 1895:** The Tesla-Westinghouse Niagara Falls Power Plant begins national electrification.
- 1897:** The Yerkes Observatory opens and becomes the birthplace of modern astrophysics.
- 1899:** The National Consumers League is founded.
- 1900:** Firestone introduces the first rubber, pneumatic automobile tire.
- 1901:** The key punch and mercury vapor lamp are invented. Ransom Olds uses the first assembly line to build the first mass-produced automobile, the Oldsmobile Curved Dash. Disposable safety razors are introduced to Americans.
- 1902:** The hearing aid and air conditioner are patented.
- 1903:** Orville and Wilbur Wright pilot the *Wright Flyer I* in the first powered, sustained mechanical flight. The United States acquires the Panama Canal. Mary Anderson patents the windshield wiper.
- 1904:** New York City opens the first subway system.
- 1906:** Herpetologist Mary C. Dickerson publishes *The Frog Book*. She will describe 20 new reptile species in her lifetime.
- 1907:** Mary Pennington becomes first head of the Department of Agriculture’s Food Research Laboratory. The telescoping curtain rod and paper towel are invented.
- 1908:** The first Model T is produced by Ford Motor Company.
- 1912:** The first electric traffic light is installed in Salt Lake City.
- 1914:** Alice G. Bryant is accepted into the American College of Surgeons. She will invent dozens of surgical tools. Caresse Crosby patents the first modern brassiere.
- 1919:** The pop-up toaster is invented to prevent burned toast.
- 1925:** Richard Drew of 3M invents masking tape.
- 1929:** Freon and the tampon are invented.
- 1931:** The Empire State Building opens its doors.
- 1933:** Albert Einstein immigrates to the United States, fleeing Nazi Germany. Famed mathematician Amalie “Emmy” Noether also leaves Germany and takes a position at Bryn Mawr College. Wide-band frequency modulation (FM) is patented. The Tennessee Valley Authority (TVA) is chartered by the U.S. Congress.
- 1934:** George Beauchamp files the patent for an electric guitar (hollow body).
- 1935:** The parking meter and surfboard fin are invented.
- 1936:** Part of a New Deal jobs program, the Hoover Dam is completed.
- 1937:** George Stibitz builds the first digital computer.
- 1939:** The first automated teller machine (ATM) is invented.
- 1941:** Hedy Lamarr patents spread-spectrum technology. Les Paul introduces the first solid-body electric guitar.
- 1941–1945:** American shipyards build 2,710 Liberty ships. The U.S. Department of Agriculture

- develops a system for mass production of penicillin.
- 1942:** The 1700-mile Alaska Highway is completed.
- 1945:** Percy Spencer invents the microwave oven.
- 1945:** The atomic bomb is perfected at Los Alamos, New Mexico. The United States drops two atomic bombs on Hiroshima and Nagasaki in Japan, ending World War II.
- 1946:** Tupperware is introduced to consumers; Brownie Wise revolutionizes marketing with the Tupperware party.
- 1947:** The U.S. Air Force demonstrates the first supersonic aircraft flight.
- 1948:** The first video game, *Tennis for Two*, is developed.
- 1949:** Grace Hopper writes the first compiler program. The crash test dummy and aerosol paint are invented.
- 1951:** Bette Nesmith Graham invents correction fluid, first called “Mistake Out.”
- 1952:** John Hetrick invents the first automobile air-bag. The plastic bread clip is invented by Floyd Paxton. The bar code is patented.
- 1954:** The Ziploc bag and TV dinners are introduced to American consumers. The first portable transistor radio, the Regency TR-1, is introduced, changing American musical culture.
- 1955:** The USS *Nautilus*, the first nuclear submarine, is launched. Jonas Salk invents the polio vaccine.
- 1957:** Gordon Gould theorizes the laser; three years later, Theodore Maiman builds the first laser.
- 1958:** Jack Kilby builds the first integrated electronic circuit. The National Aeronautics and Space Administration (NASA) is founded.
- 1959:** The first weather satellite, Vanguard 2, is launched. The Satellite for Global Navigation Satellite System is also launched.
- 1960:** The birth control pill is approved by the Food and Drug Administration.
- 1962:** Rachel Carson publishes *Silent Spring*, warning Americans about the dangers of chemical pesticides.
- 1963:** Mollie Orshansky develops the government measurement for poverty while working at the Social Security Administration. The first computer mouse is invented—it is made with wood and has two wheels.
- 1964:** The flat-panel plasma display, now common in televisions, is invented, as is the eight-track cartridge system for playing sound.
- 1965:** Artificial turf is installed in the Houston Astrodome. Ted Nelson develops hypertext, and George Sweigert patents the first cordless telephone. The compact disc, or CD, is developed.
- 1969:** The Apollo 11 lunar module lands on the moon and returns safely to earth. The Boeing 747, the first wide-body jet, has its first test flight.
- 1970:** The University of Hawaii invents the first wireless local area network.
- 1971:** John Blankenbaker invents the first personal computer. The microprocessor computer chip is produced at Intel. The first electronic mail, or e-mail, is sent by Ray Tomlinson. The first artificial heart is successfully implanted in a human.
- 1972:** Magnavox releases the first home use video game console. The Global Positioning System (GPS) is invented, though it was patented one year later.
- 1973:** Voice mail, the catalytic converter, and personal recreational watercraft are invented. Martin Cooper invents the first handheld mobile phone. Skylab, the United States’ only space station, is launched.
- 1975:** The digital camera is invented.
- 1978:** The sofa bed and microwave popcorn are invented.
- 1981:** The space shuttle is developed by NASA.
- 1982:** IBM introduces a low-cost home computer.
- 1983:** The Internet (not the World Wide Web) is first implemented by the National Science Foundation (NSF). Sally Ride becomes the first American woman in space.
- 1984:** Search for Extraterrestrial Intelligence (SETI) is founded. Chuck Hull patents the first 3-D printer. CD-ROM, DVDs, and flash memory change the data storage and music industries.

- 1985:** Microsoft introduces the Windows program.
- 1988:** Tilt-and-roll wheeled luggage is invented by pilot Robert Plath.
- 1991:** Linux and hypertext are introduced to the public, thereby simplifying coding. National Public Radio hosts the first *Science Friday*, a program devoted to science.
- 1992:** The spinning hubcap is invented.
- 1994:** BellSouth develops the first smartphone.
- 1995:** JavaScript is invented.
- 1996:** The Universal Serial Bus is introduced, as is the MP3 audio format.
- 1997:** The *Mars Pathfinder* lands on Mars.
- 1998:** The first commercially available e-reader is sold; Google appears on the World Wide Web.
- 2002:** The birth control patch is made available to consumers.
- 2003:** Toyota introduces the hybrid electric/gasoline car.
- 2005:** YouTube goes online.
- 2008:** California hosts the first Maker Faire.
- 2013:** The first autonomous, or self-driving, car moves through public traffic.
- 2017:** The Cassini-Huygens mission to Saturn comes to an end after 19 years of exploration and a myriad of astounding findings.

1. Colonial America and Enlightenment Science

OVERVIEW

Between America's colonial period and 1860, profound changes occurred in the ways people thought about the world around them. During the colonial period, Enlightenment ideas began to break through the ancient, collective veil of folklore and superstition that Western culture had used to explain the workings of the natural world. This revolution in scientific thought processes did not happen overnight, but it did develop quickly in historical terms. In the hands of individuals with the necessary time, intellect, and scientific aptitude, these groundbreaking changes in perspective promoted inquiry, experimentation, and invention that created remarkable consequences for the future of science and technology. Following the American Revolution, founders focused the use of science and technology on projects that supported the needs of the new nation. This attention to the value of technology and the promotion of invention and innovation improved America's infrastructure, allowing Americans to begin construction of a strong, viable economic system based upon several key components. The advancements of the 19th century focused on three primary areas: transportation, the harnessing of electricity, and the improvement of industrial processes. These innovations would have a major impact on America's national position in the world, its economic prosperity, and on the path of American history.

Enlightenment Science in the New World

These advances would not have been possible without the impact of the Enlightenment, a philosophical movement that completely changed the way in which people

perceived the world around them. For most people living in early colonial America, nature was an ominous, unseen force not governed by reason or measurable, calculable factors; it was, as historian David D. Hall has described it: a "world of wonders." Signs and portents appeared in the sky and with the illness, malformation, or death of animals or humans, or in unnatural occurrences such as talking animals or human infants. This ancient belief system was as real and valuable to colonial people then as the understanding of the scientific method is to us today, and the difference between the two philosophies presents a crystal-clear illustration of the effects of scientific changes that emerged during the early period of America's history.

The Enlightenment promoted the use of deductive reasoning to understand how the world worked, as opposed to the earlier system of inductive reasoning. For those familiar with the tenets of this new "Age of Reason," simply observing an event—an epidemic, for instance, or a crop failure—could not be explained in terms of society's bad behavior or the vindictiveness of an enemy. Enlightenment thinkers relied upon the gathering of data and its careful analysis, not supernatural forces. This approach had widespread implications for the future of American society, as Enlightenment thought encompassed politics, the structure of society, the idea of natural rights, religion, human relationships, economics, and many other areas, not just the scientific workings of the natural world. These different areas all worked together to create a nation that emerged as a promoter of challenging new innovation. The profound scientific and technological developments that occurred between 1607 and 1860 would not have been possible without this new way of thinking.

American Science and Indigenous People's Experience

The earliest colonists brought with them ideologies and systems that had been used in England and Western Europe for hundreds—in some cases thousands—of years. But the American environment was not the same as that of Europe. Therefore, adaptability was a necessary trait for the people who began to colonize America in the 17th century. While historical accounts relate colonists' amazement at the wealth of natural resources available, the new land was untamed and much of the flora and fauna plentiful beyond their wildest dreams, yet unfamiliar. Put simply, the new inhabitants of North America had to learn how to live there—and quickly, if they wanted to survive. Native Americans often eased the transition for those with access to and good relationships with them, both by teaching and often by actually helping to provision colonial settlements. While colonists named many of their settlements for the familiar places they had left behind, their new home required adjustment. For the earliest period, most settlers had little time for innovation beyond what was necessary to make their lives safe in their new country.

The Economic Realities

Economic gain represented the preeminent goal of the colonization process. The struggle for empire that dominated the 16th through 18th centuries focused on the conquest of land and the acquisition of wealth to build and maintain military power. The colonization of America was part of this struggle for empire, and it was not driven by individuals but by monarchies and commercial interests. While individual colonists came to America for their own personal reasons, such as religious freedom or a desire for adequate land upon which to make a better life, the “planting” of colonial settlements was funded primarily by various investors—proprietors or joint stock companies, for instance—or by royal charters. These entities intended to profit from their investments, and to do that, colonies needed to discover viable, potentially lucrative goods or processes that could be sent back to enhance the investors' bottom line and, as a result, the economic power of

their nation. The more wealth a nation could acquire, either on its own or indirectly, the more powerful it became on the world stage.

The time necessary and degree to which each colony was able to accomplish this goal depended greatly upon the primary reason the colony was founded, where it was located, and who populated it. While profit-making was always a motivation for investors, colonies such as the one settled by Puritans at Massachusetts Bay did not feel the same pressure to produce as Virginia, for instance, although both were funded by joint stock companies. This pressure often abated slowly; the first successful settlement at Jamestown in 1607 (the initial failed settlement, the famous lost Roanoke colony, was attempted in 1585) got off to a very rocky start. After harvesting timber and unsuccessfully searching for gold, in 1612, the Jamestown colony finally found a viable crop—tobacco; this commodity would fuel the economy well into the latter part of the 18th century. Each colony had its own experiences with the determining factors of success in a predominantly agricultural society: geography, climate, natural resources, and labor. Discovering ways to make colonies profitable for investors required experimentation, innovation, and revision. Although basic and primitive, the first foray of colonists into establishing settlements, taming the land, and transforming natural resources into revenue-producing products represents the earliest example of the use of science and technology by western Europeans on American soil.

These early efforts transpired under the most difficult of frontier conditions, and the tools available to colonists were virtually the same as those used elsewhere for hundreds of years. But once established, the settlements and systems implemented by colonists provided the foundation that supported American growth and innovation. As marketable products and financial resources increased, so did trade, and with an increase in trade came a better standard of living. Housing that had once consisted of one-room, rough log structures now began to have more formal floor plans, brick walls, and glass windows. The ships that carried naval stores, tobacco, rice, and other products away from America returned from Europe with fabrics, pottery, paper, and luxury goods such as fine soaps and gloves. Ships from the Caribbean colonies

brought sugar, molasses, and slaves to the mainland colonies and returned to their own ports with barrel staves, vegetables, flour, and salted meat and fish.

This burgeoning trade came at a cost, however. Through a series of navigation acts, the mercantile system existing between England and her mainland colonies dictated that only raw materials could be exported from America and that finished, or manufactured, goods must be imported to the American colonies from the British Empire. While the home manufacture of some items was clearly necessary, these products were only for personal use; items such as knitted stockings and other similar finished articles of clothing, for example, were not to be manufactured on a large scale and exported to England or any other country. In short, mercantilism was the economic engine that ran the colonial system, and for the integrity of the system to be guarded, it had to remain in a closed loop. This prohibition of large-scale manufacturing of finished goods suppressed the need for much technological innovation during the colonial period.

The Challenges of a Colonial Endeavor

In the colonies' agriculture-based society, labor was scarce. Therefore, time and energy resources went to production, not innovation. Simply put, the farmer's (or blacksmith's, or printer's) priority was feeding his family, not designing new tools or systems. In addition, little capital was available to fund some of the more viable technology-based businesses such as foundries or mining operations, and there was little need. England's Iron Act (1750), for example, limited American colonial innovation in the foundry business by prohibiting plating operations, establishment of new forges for the production of tools, the building of new mills, and the production of hardware. The Iron Act restricted America's output of iron exports to raw material only. Furthermore, in accordance with the mercantile system, exports were allowed only to the British Empire. With such restricted products and a closed market, there was little incentive for busy workmen to innovate.

Science and technology did expand in areas not related to manufacturing, however. As the basis for a primarily agricultural society, the study of botany and agronomy proliferated as farmers and plantation owners

attempted to grow better crops and harvest and process them more efficiently in hopes of increasing their market value. As markets changed due to weather, disease, pests, or political crises, planters experimented with new crops to maintain their production and income. For example, the French and Indian War (1754–1763) resulted in an increase in the cost of shipping exports, which caused many South Carolina rice planters to add indigo as a secondary crop. Several years of experimentation by agronomists such as Eliza Lucas Pinckney revealed that indigo could be grown in conjunction with rice, yet it was easier to ship and more profitable. Further experimentation resulted in better strains and more efficient and effective processing methods, which only served to increase the profitability of the crop. In Virginia, tobacco was the cash crop that kept the colonial economy running, fueled by a growing reliance on slave labor. However, tobacco is notoriously hard on the soil. After many decades of extensive production in Virginia, farmers were forced to search for an alternative to tobacco to compensate for the dwindling land available to support its culture. Experimentation and improvement resulted in the discovery of wheat as the most viable secondary export crop. In the northern colonies, where large-scale plantations were not feasible due to climate or geography, naval stores (the production of lumber and timber for ships' masts, turpentine, and tar) provided a lucrative economic base. This supported and eventually expanded into shipbuilding as an important industry in the New England colonies and represents one instance where the production of raw materials for export existed alongside a permitted manufacturing system.

The Wonders of the "New World"

While the previous examples illustrate the role of science and technology in the growth of the American economy, evidence is even more visible in the study of the natural world of zoology, geography, geology, astronomy, physics, chemistry, and biology. The interest in and study of these disciplines created a vivid dividing line between reliance upon "wonders" and a better understanding of the universe based upon deductive reasoning and verifiable facts. This gained insight resulted not only in a new way of looking at the world; it also promoted innovation and invention.

One of the best-known examples of someone interested in such scientific thought is Benjamin Franklin. Almost every schoolchild knows the story of Franklin's electrical experiment with the kite and the key, an exercise that led to the invention of the lightning rod; this invention saved many a building from destruction by fire. Franklin's 1752 experiment and discovery that electricity operates in a "fluid" manner by flowing between positive and negative charges is generally considered the beginning of American scientific progress, and many of the terms related to electricity, such as "battery," "positive," "negative," "charge," and "conductor," were coined or used in a new way by Franklin. However, Franklin also unlocked a secret of the natural world that has become indispensable; his experiment became the basis for one of the most important components of America's future scientific and technological development—the harnessing of electricity. Franklin's practical, fertile mind and inquisitive nature led him to invent numerous helpful items including bifocal lenses, the flexible catheter, swim fins, and an improved stove. He also invented the less well-known but curious and beautiful musical instrument, the glass armonica, which produces a haunting sound due to the oscillation of sound waves produced by the touch of a finger on rotating glass bowls of various sizes. Franklin was so involved with natural philosophy (the 18th-century term for the study of nature) that in 1743, he founded the American Philosophical Society, an organization committed to scientific study and inquiry that has operated up to the present day.

Thomas Jefferson became a member of the American Philosophical Society in 1780, representing the arrival of another generation of eminent American scientists. Jefferson's interests ran from architecture and agronomy (it has been said that he counted every pea grown in his gardens to analyze and improve his farming practices—the man loved peas) to zoology. Besides agronomy, Jefferson had an intense curiosity about natural history; he collected zoological specimens, including dinosaur bones, and he owned the Natural Bridge, a geological formation located in what is now Rockbridge County, Virginia. Like Franklin, Jefferson was also an inventor, although most of his inventions, such as the portable writing desk, swivel chair, and

pantograph, a device that copied documents as the author wrote them, were improvements of existing articles. Jefferson's most original and widely useful invention was a new design for a moldboard plow, the "Mouldboard of Least Resistance," which earned him accolades from learned societies in England, Italy, and France. As president of the United States, Jefferson ordered the Lewis and Clark expedition into the Northwest and the lesser-known Dunbar and Freeman expedition, which explored the southern reaches of the newly acquired Louisiana Territory. These endeavors gathered geographic information, collected climate and weather data, documented new types of flora and fauna, and identified Native American settlements and cultural practices, providing valuable scientific information for the understanding of the new nation.

With the finalization of the U.S. Constitution in 1787, the Founding Fathers began the process of building an American economy that would support the needs of the new nation. To this end, the government enacted new laws designed to improve infrastructure, promote industry, and protect American export markets. In 1790, Congress established the U.S. Patent Board, which issued its first patent that same year. The board consisted of three members, and Thomas Jefferson's duties as secretary of state included the role of patent commissioner.

The Dawn of the Industrial Revolution

The beginning of the Industrial Revolution in America coincided with the birth of the new nation. Until that time, most industry consisted of home manufacturing and not industrial production. The way in which this home production of goods functioned changed over time. Early on, one person might produce an item from start to finish. Later, the "putting-out" process emerged. In this type of production, the item passed through many hands, each person creating one part of the item before it was passed along to an individual responsible for handling the next step in the manufacturing process. Work was therefore "put out" to as many craftsmen—or women—as necessary to produce the finished product for the investor. At the dawn of the Industrial Revolution, mechanization began to replace the "putting-out" system.

American independence also ended the mercantile system and afforded creative Americans the opportunity to expand commerce and strengthen the national economy. This required expansion of the new nation's infrastructure and improvement and growth in agriculture and industry, bringing production of many items out of the home and into the factory and marketplace. The era of the Early Republic through 1860 brought innovation in three major areas: transportation, the harnessing of electricity, and the growth of industry. These three areas operated in conjunction with one another to develop a robust economy and bolster the international status of the United States.

The earliest use of machines for manufacturing purposes began with the textile industry. Once dominated by factories in England, the end of the American Revolution and the aspirations of the new nation opened opportunity for the United States to engage more fully in textile production and export. The first American mill for spinning cotton thread was built in 1793 by British immigrant Samuel Slater, who had worked in the textile industry in England. Slater had been lured to America when he learned that the Pennsylvania Society for the Encouragement of Manufacture and Useful Arts offered cash prizes to inventors who improved textile machinery or processes. Soon, Slater built mills in New England and eventually founded the mill town of Slaterville in Rhode Island. Slater's wife, Hannah, invented two-ply thread and in 1793 was the first woman to receive a U.S. patent. Construction of F. C. Lowell's power loom textile mill near Boston, Massachusetts, began in 1814; by 1821, the mill and the factory town of Lowell, Massachusetts, were complete. The machinery that ran both the Slater and Lowell businesses was not invented in the United States but was based upon designs created in England. What is remarkable about the equipment is that it was all built without blueprints or design plans; both Slater and Lowell recreated their machines from memory based upon English examples they had seen.

Both factories created widespread changes in American culture. Slater virtually jump-started the Industrial Revolution in the United States, the effects of which reached out to encompass almost every sector of society. Lowell's factory system revolutionized the way goods were processed, rapidly replacing the

"putting-out" system. When Lowell's factory was completed, he staffed it with young women who were drawn to the factory's location near Boston from their homes in the country. Lowell provided housing and other amenities for the young ladies while allowing them to participate in waged work. The arrangement pushed the envelope of what were considered proper boundaries for a young woman at the time; it also started a trend of country-to-city movement for participation in wage work.

King Cotton

Eli Whitney and Catharine Littlefield Greene's 1793 invention of the first commercially viable cotton gin was one of the most important contributions to the rise of the American textile industry. Whitney's invention set off the boom in cotton agriculture that would continue to expand for many decades; his subsequent implementation of the use of interchangeable parts in the manufacturing process would influence the path of the Industrial Revolution in America. Plantation agriculture dominated the South, and with a new way to more rapidly and efficiently process the bolls, more cotton could be grown for the textile industry. Climate, availability of arable land, and excellent growing conditions in the South allowed for the plantation system to expand, while limited arable soil and less agreeable climate encouraged industry to proliferate in the Northeast. Cotton could now be grown, processed, and milled more efficiently. The labor shortage that had prevented large-scale manufacturing in the North had been solved via new milling and looming machinery and rural-to-city movement for waged work. Labor shortages in the South were now filled via the institution of slavery. Both of these trends had profound effects upon the rise of industry in general and the movement of people from country to city; they also promoted the growth of the Cotton South because the two systems—agricultural and industrial—depended upon each other. By the middle of the 19th century, this tension would erupt in warfare.

Until the 1850s, all textiles were sewn by hand, but in 1846, Elias Howe received the first American patent for a mechanized sewing machine. In 1851, Isaac Singer developed what would soon become the

first commercially viable sewing machine, a treadle-powered model that used Howe's patented two-thread lockstitch method. Singer successfully mass-produced his machine, even developing an installment credit plan to boost his sales, but he soon found himself in a patent battle with Howe. Singer lost the lawsuit and was forced to pay royalties to Howe on every sewing machine he manufactured and sold. Howe became a very wealthy man, and the Singer name has been associated with sewing—particularly home sewing—ever since. At the same time, the example of the sewing machine marks a critical time in the growth of the Industrial Revolution in America and the impact of mass production on the American home.

The Transportation Revolution

Once goods were manufactured, they had to be transported to consumers. Reliable profits from technological advancements in manufacturing depended upon the ability to sell products at a reasonable price. The early 19th century witnessed transportation advances that made sending goods to market easier and less expensive than ever before. Prior to the early 19th century, goods had to be transported over land and along natural waterways. This arrangement worked well but was slow and expensive, and it burdened both producers and consumers, especially those in out-of-the-way places. Early attempts at canal building had begun in the late 1700s with the construction of a portage canal on the lower Susquehanna River in Pennsylvania; the project was completed in 1797. George Washington, Thomas Jefferson, and James Madison were part of a 1785 canal-building project under the auspices of the Potomac Company, and many other investors experienced varying degrees of success with their small canal-building ventures.

It was not until the completion of the Erie Canal in 1825 that the era of canal building was truly realized. Funded by the state of New York and begun in 1817, this 363-mile long waterway far surpassed the longest existing canal, the 27-foot-long Middlesex Canal in Massachusetts. Completion of the Erie Canal created a shipping lane from the western interior on Lake Erie all the way to New York and the Atlantic, opening western commerce to Europe and beyond. It also

opened up the West to importation of more readily available goods from points east. At the same time, transportation costs dropped; in some cases, the difference between the previous overland route and the Erie Canal route amounted to as much as 95 percent. The construction of the canal itself may have been an engineering wonder for its day, but the entire project was dug without the use of heavy equipment. By 1850, the state of New York had added eight additional canals that flowed south from the Erie.

Between the years 1815 and 1860, almost 4,300 miles of canals were built in the United States at a cost of \$189 million, most of which was funded by state governments. Canals represented a great boon to local, regional, and national economies. Construction required engineers, and canal construction, maintenance, and operation also required labor, material, and support services. Once completed, canal boats had to be towed by horses or mules that walked along the sides of the canal; those animals required care and handlers. Monitoring, repairs, and maintenance were constant expenses that required manpower to manage and execute. Therefore, in addition to the economic benefits derived from the ability to ship goods long distances over water at a heretofore unprecedented speed, benefiting local farmers as well as big-city vendors, canals provided jobs and income for a wide variety of workers along the entire length of each waterway.

Canals were not the only transportation improvement in the early 19th century. One drawback of the canal system was that these waterways could not accommodate large boats—only those with shallow drafts that could be towed by animal power. The invention of the steam engine and its subsequent use in both the locomotive and the steamboat facilitated the movement of people and cargo over a network of railroad tracks, rivers, and canals. While the earliest steam-powered vessels had been designed in the previous century, it was not until 1807 that Robert Fulton created what would become the nation's first commercially viable steamboat. After numerous adjustments and improvements to his original design, Fulton's *Clermont* chugged along the Hudson River on its way from New York City to Albany and back. The steam-powered vessel revolutionized riverine transportation of people and goods and encouraged the proliferation

of steamboat-powered movement of cargo and passengers along both major thoroughfares such as the Mississippi River as well as numerous smaller rivers and canals.

The nation's first steam-powered locomotive was designed by Peter Cooper of New York for the Baltimore and Ohio Railroad. Baltimore, Maryland, had been an important harbor, but construction of the Erie Canal threatened to take business away from the city. Beginning in 1828, B&O Railroad executives ordered the construction of tracks, and by 1830, they hired Cooper to build a steam locomotive, as it had become clear that their earlier plans for a horse-drawn train would prove inadequate to the task. From the establishment of this first 13-mile-long railroad in 1830, the total number of track miles expanded to total 30,000 by 1860, crossing the Appalachian Mountains and extending to connect the Midwest with the rest of the country.

The 1830s also brought advances related to the harnessing of electricity. Franklin's 18th-century discovery of the "fluid" nature of electricity and his related experiments were only the beginning of exploration and invention that would make the use of electricity commonplace. As early as 1831, Joseph Henry experimented with electromagnetic induction, which paved the way for the creation of generators and electric motors. While Englishman James Faraday usually gets the credit for this discovery, his work coincided with Henry's. Unfortunately for Henry and his legacy, Faraday published his work and obtained the first patent. Henry was selected, however, as the first secretary of the Smithsonian Institution upon its founding in 1846.

In the early 1830s, following a trip to Europe that undoubtedly influenced his interest, Samuel F. B. Morse designed his first prototype for the telegraph, a device that transmits messages via electrical impulse over a wire using a system of dots and dashes. Morse received funding for his invention and collaborated on the creation of Morse code with a fellow inventor Alfred Vail. In 1844, funded by a \$30,000 congressional appropriation, Morse completed his first telegraph line. Morse's first message traveled the 38 miles between Washington, D.C., and Baltimore, Maryland. By 1860, the United States' telegraph system contained

approximately 50,000 miles of telegraph line, and in that same year, Congress enacted the Pacific Telegraph Act of 1860, which authorized appropriations and the acceptance of bids to complete a transcontinental telegraph line.

The Consequences of Change

Between the colonial period, through the Revolutionary Era and the Early Republic and into the Antebellum period, American science and technology experienced revolutionary growth. This growth began with the simple, pragmatic need to merely stay alive in a new world and developed into the conscious creation of a national infrastructure that would support the needs of a new nation and improve the lives of its citizens. It eventually expanded to the development of machinery, agricultural and industrial production systems, communications, and the use of new power sources such as steam and electricity to power those systems. Some early scientists studied agronomy or gazed at the stars, explored paleontology, or invented useful items. Some were at the very forefront of American economic and cultural growth, manufacturing and transporting goods, transmitting information, and making daily life easier. These advances would be reconsidered, revised, and built upon over time; they had implications for the establishment of the United States, for the advent of such turning points as the Civil War, and in some cases for its outcome.

The various aspects of science and technology in the growing United States fit together like pieces of a fantastic design, all of which are intricately interwoven within the fabric of history. Philosophy, politics, population trends, and cultural change all contributed to the evolution of technology in America. The transition from pre-Enlightenment beliefs in "wonders" and other folk doctrines to the widespread understanding of deductive reasoning and the relationship between cause and effect fueled inquiry; indeed, it affected the very way in which individuals thought of themselves and their abilities. The increasing stabilization of the American colonies and the onset of Revolution offered opportunity for the expansion of markets that could be enhanced by forward-thinking philosophes and inventors. Early on, the U.S. government, as well as the private sector, encouraged the

invention, manufacture, and exportation of goods to strengthen the new nation via legislation and competition. The Industrial Revolution made good use of the development of newly invented machinery and processes, and by the end of the Antebellum period, the level of technological advancement in America would have astounded the early colonists.

These changes came with consequences, some intended, some not, but all were interrelated with the course of American history. Early textile manufacturing set in motion the movement of workers from farm to factory, which began a redistribution of population that would lead to the exponential growth of cities in the decades to come. The single example of cotton culture and manufacturing vividly illustrates the profound effect that the evolution of technology in America could have not only on the nation's economy but a seminal effect upon politics and the very question of the perpetuation of the Union. The acceleration of technological innovation and the economic and scientific advances that accompanied it set the United States on a path that the founding generations set in motion but which they never could have envisioned.

American Philosophical Society

The American Philosophical Society (APS) was the United States' first learned society. It emerged from a society that Benjamin Franklin founded in 1743. Its goal, according to Franklin, was to improve what he

called "the common stock of knowledge." Its members included a who's who of Americans and Europeans such as George Washington, John Adams, Alexander Hamilton, Thomas Jefferson, the Marquis de Lafayette, Baron von Steuben, and General Tadeusz Kosciuszko.

The APS focused on what was termed "natural philosophy" in its early days, meaning both scientific and technological studies. Thus, the society aided the general economic independence of the colonies through aiding the development of transportation, agriculture, and manufacturing. Additionally, the society gained great international acclaim through its advances in astronomy, one example of which was David Rittenhouse's plotting of the transit of Venus.

The society fell on dark days during the period of the American Revolution. However, with the aid of the state of Pennsylvania and the work of Samuel Vaughan and Francis Hopkinson, it revived quickly. Pennsylvania gave the Society a charter allowing it to correspond with scholars and scholarly institutions at any time on what it defined as legitimate business in peace and war. Pennsylvania also gave the APS land on Independence Square, on which it built Philosophical Hall (1785–1789). In the revived APS, each elected member became a participant on one of the following committees: Geography, Mathematics, Natural Philosophy (physics) and Astronomy; Medicine and Anatomy; Natural History and Chemistry; Trade and Commerce; Mechanics and Architecture; or Husbandry and American Improvements.

Among its many illustrious members, perhaps, Thomas Jefferson was the most illustrious. He became a member of the APS in 1780 and one of its counselors in 1791. Jefferson was a very active member of the Society. His work there demonstrated his vast knowledge and curiosity. He studied the Hessian fly, a threat to the American farmer, and encouraged a collection of mammoth skeletons by William Clark. Of course, the Lewis and Clark Expedition was his most famous undertaking with the APS. Jefferson connected Lewis with APS members who advised him on the upcoming expedition. Indeed, their journals and many of their collected artifacts are stored in the APS. In 1797 Jefferson became vice president of the United States for

one four-year term and president of the APS for the next 18 years.

From the early independence period until about 1840, the APS remained a private concern. Nevertheless, it acted like a national institution—an academy of science, a national library, a museum, and a patent office. The APS provided valuable counsel to government officials. Additionally, the Society not only became the pattern for other learned societies but also spun off specialized organizations in many fields such as history, chemistry, and agriculture. It also gave space to other institutions, artists, cultural institutions, and sciences, including the University of Pennsylvania, Charles Willson Peale's museum, and Thomas Sully's studio, among many other cultural and even charitable organizations.

The APS's prominence is reflected in its membership over the years. It has included luminaries from many fields. In addition to a number of founding fathers and other 18th-century luminaries, its later members included John J. Audubon, Robert Fulton, Charles Darwin, Thomas Edison, Alexander von Humboldt, Louis Pasteur, Albert Einstein, Robert Frost, George C. Marshall, and Linus Pauling. Female members have included the Russian princess Yekaterina Dashkova, president of the Imperial Academy of Sciences in St. Petersburg, Russia; Elizabeth Cabot Cary Agassiz, Marie Curie, Gerty T. Cori, and Margaret Mead.

The APS has continued to grow, and its illustrious membership has aided in that growth. In the 1930s, for example, it began to develop in new directions, including offering a research grant program. A number of its small grants resulted in academic publications. Clinical medicine benefited from another program, and scientists were aided in conducting research into diseases. Currently, there are five separate grant programs that have grown from these earlier grants.

The APS's publications program has included a journal, a monograph series, memoirs, and a yearbook. Its library eventually required its own building. In 1981, Library Hall was erected, making it the third of the APS's buildings.

The Society acknowledges important accomplishments in a number of ways. It elects members who

John Bartram, a cofounder, with Benjamin Franklin, of the American Philosophical Society, posed for this portrait in or around the time of the Revolutionary War. His botanic garden, about three miles from the center of Philadelphia, Pennsylvania, is frequently cited as the first true botanic collection in North America. (Library of Congress)

have made superior achievements, and it presents medals and prizes. Among these prizes are those in navigation, astronomy or natural philosophy, contributions to American or European cultural history, neurobiology, and many others.

The APS library is the result of more than 270 years of collecting, including of material from the early days of the United States to the present. It holds more than 13 million manuscripts and books. It also collects scientific artifacts, including patent models. Of course, there are rare books in it, as well as photos, maps, and various paintings.

Particularly interesting and valuable holdings include William Penn's 1701 Charter of Privileges extending the right of people to enact their own laws. The chair that Thomas Jefferson used when writing the Declaration of Independence is also in the APS. There are also historic paintings on display, including one of Gilbert Stuart's famous portraits of George Washington.

Charles Willson Peale, the most famous and favorite artist of his time, housed his personal museum in the APS. Peale was noted for his promotional skills, which seem to have inspired the great P. T. Barnum himself. Indeed, he was not only a famous artist but also an inventor, naturalist, and educator. He once found a mastodon in upstate New York and sent it to the APS. He even charged people an extra half dollar to see it. For a time, people were obsessed with the "mammoth," and products like bread and cheese came in "mammoth" sizes. Cheese makers in Massachusetts even sent President John Adams a mammoth cheese.

Peale's museum collection became the basis for the APS's museum. From its founding in 1784, it was not only one of the first museums in the United States, it was one of its more popular and a lasting success. The collections covered many fields and included not only Peale's portraits of famous Americans but also stuffed birds and the mastodon.

The spirit of that museum continues to provide what it has called "rational amusement" to the populace. The APS museum has changing thematic exhibitions on history, art, and science, with a strong emphasis on the early history of the United States and, more particularly, Philadelphia. The museum exhibits

include rare manuscripts and books and examples of art and science, specimens of natural history, and other curiosities. The museum borrows works from other institutions as well.

For over 270 years, the APS has led the way in scholarly research and presentation. It has lived up to the hopes and goals of its founder, Benjamin Franklin, in bringing knowledge and understanding to the people. It continues to expand its reach and accessibility, promoting research and knowledge in numerous fields and to improve the "common stock of knowledge."

Primary Document: Memorial of the American Philosophical Society Favoring an Exploration of the Alaskan Coast (1868)

In response to financial difficulties and in an effort to keep its Alaskan Territory from the British, Russia sold Alaska to the United States in 1867 for just over \$7 million. Called "Seward's folly" at the time because then-secretary of state William Seward approved the purchase, the territory was put under the jurisdiction of the U.S. Army and known as the Department of Alaska. The area was, at the time of its acquisition,

largely unexplored by both the Russians and the Americans. On February 26, 1868, the American Philosophical Society reached out to the U.S. Congress with the aim of exploring the new territory in the "Interests of both Science and Commerce."

To the Honorable Senate and House of Representatives of the Congress of the United States

The Memorial of the American Philosophical Society Respectful Represents:

That the subject of the acquisition of the Alaskan Territory has been brought before this Society in its relations to science and the discussion resulted in the unanimous adoption of the following Preamble and Resolution:

“Whereas there is reason to believe that the North Western Territory recently ceded to the United States by the Russian Government possesses Resources in productions and naval facilities of much greater value and importance that has heretofore been supposed, the early development of which by exploration in Geology and Natural History is deemed to be of high importance to the Interests of both Science and of Commerce. Therefore—

Resolved that the Officers of this Society be requested to sign and transmit to Congress a Memorial asking the earliest possible action for the

commencement and execution of proper examinations upon the coast and within the said Territory by Officers of the Coast Survey and others of competent Scientific ability and experience.”

In pursuance of the direction of the above Resolution we very respectfully present this expression of the views of the Society as their Memorial, for the consideration and action of Congress and pray that adequate means may be adopted to make the explorations of the Government productive in the interests of Science, as well as those of Commerce, and of the extension of the area of freedom and civilization.

Philadelphia, February 26th, 1868

Astronomical Almanacs

An almanac is an annual publication running through a year, providing information on a wide range of topics such as weather forecasts, tidal phenomena, planting dates for farming, eclipses, moon phases, religious festivals, and national holidays. Although at first almanacs had an eminent astronomical use (thence the name), as time went by, especially in America, they acquired a much more utilitarian focus, including practical information such as deadlines for the payment of taxes.

The first American almanac was *An Almanac for New England for the Year 1639*. Published in Cambridge, Massachusetts, it was the work of William Pierce of Harvard College. The first recorded usage of the term “almanac” was by English philosopher Roger Bacon in 1267, but its etymology (that is, the origin of the word itself) is unknown. The almanac’s origins can be dated back to mid-16th-century England with the publication of the almanacs of John Dade, Anthony Askham, Thomas Buckminster, and Gabriel Frende. In England, by the 17th century the popularity of almanacs was such

that 400,000 copies were sold every year. After the Bible, they were the bestselling books. Richard Allestree’s almanac, which ran from 1617 to 1643, was a favorite.

The most relevant almanacs in the 18th century were: Nathaniel Ames’s *Astronomical Diary and Almanack* (Dedham, Massachusetts; 1725–1775); James Franklin’s (Benjamin Franklin’s brother) *Rhode-Island Almanack* (from 1728 onward); Benjamin Franklin’s own *Poor Richard’s Almanack* (1733–1758); and Benjamin Banneker’s (1792–1797). The longest-running almanac was Robert Bailey’s, first published in 1792 and later renamed *The Old Farmer’s Almanac*. There also existed comic almanacs such as *Poor Robin’s Almanack* or John Tully’s of Saybrook, Connecticut (the latter spanning from 1687 to 1702).

Although Franklin’s *Poor Richard’s Almanack* is often mentioned as the quintessential American almanac, it was far from being the longest running or the bestselling. Actually, Ames’s had a much larger number of readers—60,000—in contrast to the 10,000 circulation of *Poor Richard’s*. Ames’ *Almanack* featured zodiac signs, movable feasts, poems related to each month, anniversaries, and weather predictions.

To better understand the extent of the influence of almanacs in the colonial period, one has to take into account the other sources of information at the time—or rather, the lack of these. In the days before radio, television, and the Internet, obtaining reliable information was a difficult task. Newspapers were available, but those in rural areas (and most of the population did not live in urban centers) found it difficult to access them. Often, newspapers traveled slowly, and they were received in rural areas after weeks of delay, therefore rendering whatever information they might contain obsolete and out of date by the time they were read. Getting some news was relatively easy throughout the period, as it could be obtained from a multitude of sources—a traveler passing through town, a peddler, or acquaintances and neighbors. However, obtaining *reliable* news was altogether more complicated.

An almanac included a monthly calendar as well as tables of astronomical events. The astronomical knowledge contained in the first almanacs soon gave way to more scientific data in time. Seasonal changes were duly recorded; the daily weather was a topic of much interest. Nevertheless, weather predictions, despite the painstaking recording of weather phenomena, were mostly unreliable and inaccurate. Buyers of almanacs used the included blank pages as personal diaries, and those that have been preserved are invaluable sociological documents. One user of almanacs in this way was George Washington.

Typical information contained in almanacs included anniversaries, interest tables, exchange and postal rates, population tables, recipes, interesting trivia pieces, anecdotes, opinion essays, songs, ballads, proverbs, jokes, fictional works, statistical information, poems, home medical advice, and tips on housekeeping and farming. Other useful information was where courts were located and the days on which court was held, or information on government officials. With all the detail and wealth of information that they included, almanacs were a most useful compendium of all the information a citizen might need on a daily basis.

Almanacs constitute a window to popular culture and people's interests and concerns. For example, the

presence of astrological tables was due to the widespread folk belief in the influence of the planets on human behavior as well as on natural occurrences. The planets were also described, and tables on the movement of planets were featured. Gradually, American almanacs put a much greater emphasis on practical matters and less on astrology, in contrast to their British counterparts. This emphasis on practicality was due, to a great extent, to Puritan influence, as Puritans abhorred anything that did not have a practical purpose.

While many of the ideas contained in almanacs came largely from Europe, Benjamin Franklin, who espoused deist beliefs (the idea that observation and revelation is the key to the discovery of the existence of a supreme being or god), conveyed these newer ideas in his almanac. During the American Revolution, the publishers of some almanacs made clear their views and supported the revolutionary cause, as did Nathaniel Ames. *Ames' Almanack* explained to its readers how to make gunpowder. Later on, Benjamin Banneker, a renowned supporter of the abolitionist movement, chose to print in his almanac essays espousing that cause. Thus, almanac publishers could sway the public's stance on a given topic.

Almanacs continue to be popular in modern times. More often than not, they are now intended for a specific audience or address a specialized topic.

Primary Document: Aphorisms from *Poor Richard's Almanack* (1732–1758)

Benjamin Franklin wrote and published Poor Richard's Almanack from 1732 to 1758 under the pseudonym "Poor Richard" or "Richard Saunders." In addition to containing a wealth of information about weather and astronomical phenomena as well as agricultural notes, Franklin sprinkled his almanac with pithy aphorisms, many of them still relatively well known. The following is a selection of the best known of these aphorisms.

"There are no gains without pains."
 "One today is worth two tomorrows."
 "Have you something to do tomorrow? Do it today."
 "Industry pays debts while despair increases them."
 "Women and wine, game and deceit, make the wealth small and the wants great."
 "Keep thy shop and thy shop will keep thee."
 "The wise man draws more advantage from his enemies than the fool from his friends."

"Pride dines on Vanity, sups on Contempt."
 "A learned blockhead is a greater blockhead than an ignorant one."
 "The noblest question is the world is What good may I do in it."
 "The learned fool writes his nonsense in better languages than the unlearned, but still it is nonsense."
 "He that lives on hope will die fasting."
 "'Tis hard but glorious to be poor and honest."
 "Tricks and treachery are the practice of fools that have not wit enough to be honest."
 "Many have quarreled about religion and never practiced it."

Banneker, Benjamin (1731–1806)

Benjamin Banneker was a free African American, mathematician, astronomer, abolitionist, and an almanac author from Baltimore, Maryland. He published six almanacs between 1792 and 1797, as well as papers on a variety of subjects.

Banneker's mother and father were freed slaves. Banneker's grandmother taught him how to read. He became a very avid reader and would read the Bible to his family every evening. As a child, he lived on a farm with his family and attended a Quaker country school—his only exposure to formal education. He was an avid self-learner and would later teach himself literature and history. He also taught himself geometry along with any other mathematical subject he could find. He borrowed many textbooks to learn these subjects. Often he composed problems for himself to test his mathematical knowledge. When he was 22, he built a fully functional clock, based on a pocket watch that he had been given. It continued to keep

time until he died. He inherited his family's farm and made it into a success by growing and selling tobacco. He used his love of math and machinery to create an irrigation system that would properly water his crops.

His interest in astronomy blossomed when he was 58 due to his neighbor, George Ellicott, who was a fellow mathematician and amateur astronomer. He gave Banneker books on astronomy as well as a telescope. Banneker became immensely interested in the stars and other celestial bodies. He studied eclipses and provided ephemerides—tables noting the positions of celestial objects at certain times—for his almanac. His ephemerides aided sailors and farmers greatly. Now the seas were easily navigable, and the accuracy of sowing seeds at the right time of year was increased. Banneker was also Ellicott's field assistant in scientific endeavors. One included the land survey of the District of Columbia, which provided the first glimpse of the land where the future capital of the United States would be built. All of these scientific outings also helped him to write his almanacs.

Banneker's other contributions to the almanac dealt with the antislavery movement. He wrote to Thomas Jefferson, the secretary of state at the time, and criticized him for owning slaves. He compared it to the Americans being enslaved by the British. Banneker believed Jefferson to be an amiable man and open to conversation on African Americans being viewed as more than mere property. He included a full copy of his almanac with his letter. Jefferson's response to the letter was positive, and he passed the almanac on to the French Academy of Sciences to display. Jefferson hoped this display would act as significant proof of African American intelligence, and though Jefferson and Banneker continued to correspond frequently and some of the letters were published in Banneker's almanacs, Jefferson never voluntarily freed his own slaves.

The abolitionist community in Maryland also assisted in the publication of Banneker's almanacs. They believed this was a prime way to show the country the works of an African American. They also believed that it would help show that black intellectual abilities were on par with all other races. This is a topic that Banneker addresses in one of his most notable quotes: "The colour of the skin is in no way connected with strength of the mind or intellectual powers." In 1797 he published his final almanac. Even so, he still continued creating ephemerides. Banneker would, in his later years, publish writings on bees and the life cycle of locusts.

Banneker died in 1806 at the age of 74 in his log cabin. He had had a lifelong issue with alcoholism, which significantly worsened in his later years. The disease may have played a significant role in his death. Suspiciously, during Banneker's funeral, his cabin

was burned down. The cause of the fire was never discovered. His clock, many writings, and most of his possessions perished in the fire. His family was only able to recover a few of his books and belongings. Most of his remaining property found its way to museums and private buyers. Many of them would eventually donate Banneker's belongings to museum collections to preserve them.

After his death, many myths and legends arose about him, one of them being that he had actually helped build Washington, D.C., in addition to surveying its land. Another said that he built his clock after being inspired by a sundial. Banneker's work was highly influential and provided a stage for abolitionists to get their messages of equality out effectively. His work also provided aid to the everyday man for everyday endeavors. His almanacs remain some of the most influential scientific work to come out of the early United States.

Primary Document: Letter of Thomas Jefferson to Benjamin Banneker, Expressing Jefferson's Belief That Blacks Had Talents Equal to Other Races (1791)

African American inventor, author, naturalist, and surveyor Benjamin Banneker was hired by Thomas Jefferson to undertake a survey of western New York. The two men engaged in a correspondence upon a

variety of matters, including their ideas about racial equality or lack thereof. Jefferson's letters to Banneker reveal inconsistencies in the Virginia slave owner's beliefs about black Americans.

Philadelphia Aug. 30. 1791.

Sir,

I thank you sincerely for your letter of the 19th. instant and for the Almanac it contained. No body wishes more than I do to see such proofs as you exhibit, that nature has given to our black brethren, talents equal to those of the other colours of men, & that the appearance of a want of them is owing merely to the degraded condition of their existence both in Africa & America. I can add with truth that no body wishes more ardently to see a good system commenced for raising the condition both of their body & mind to what it ought to be, as fast as the imbecillity of their present existence, and other circumstance which cannot be neglected, will admit.

I have taken the liberty of sending your almanac to Monsieur de Condorcet, Secretary of the Academy of sciences at Paris, and member of the Philanthropic society because I considered it as a document to which your whole colour had a right for their justification against the doubts which have been entertained of them.

I am with great esteem,
Sir,

Your most obedt. humble servt.
Th. Jefferson

Bifocals

Bifocals are eyeglasses with two distinct lenses, each to correct a different optic problem. Generally, they suit people who have a problem focusing on nearer objects—"presbyopia"—but who also require a correction for "myopia" (nearsightedness), "hyperopia" (farsightedness), and/or "astigmatism," an inability to focus on an object to get a clear view instead of a blurred one.

Although there is some dispute, most scholars who study the issue hold that Benjamin Franklin invented bifocals. In 1824, the inventor of the trifocals, John Isaac Hawkins, came up with the term "bifocals," attributing their invention to Benjamin Franklin, as did the editors of the *Gazette of the United States*, an early Federalist newspaper.

There is a story that Franklin grew tired of switching from one pair of glasses to another and so found a way to bind two different lenses into the same pair of glasses.

Benjamin Franklin invented bifocals in 1824. Here, he holds a paper with his drawing for the invention, his face reflected in a mirror so that the paper can be easily viewed. In 2018, estimates showed 75 percent of adults used some sort of vision correction. (Bettmann/Getty Images)

Originally, the distance lenses were placed on top and the reading lenses on the bottom. For some time, people followed the pattern set by Franklin of melding two lenses together. Eventually, improvements came about because of the fragility of bifocals. Near the end of the 18th century, Louis de Wecker invented a means for fusing the two sections together to strengthen the glasses. John L. Borsh later patented the process in 1908.

Currently, a majority of bifocals have a reading lens molded into a previously constructed primary lens. There are many different shapes and sizes for the reading lens. Additionally, progressive lenses are replacing bifocals, generally because they do away with troublesome lines and also serve people's vanity in not making it so obvious that they are wearing bifocals, which many still identify with old age.

Progressive lenses may also ease the problems that many people have with bifocals. Some people experience headaches or dizziness from wearing bifocals. Moreover, the small area allowing for reading in many bifocals can take some time and adjustment to use. The reader must move his or her head up and down or move the eyes to find the text. This can be great trouble given the straight-on view one needs to use for reading computer monitors. Trifocals or monofocals can help solve this problem.

The first patent priority date for progressive lenses went to Owen Aves in 1907. Aves's design differed from that of modern progressive lenses because it had a conical back surface coupled with a front portion that was cylindrical. It also had axes that opposed each other to allow a power progression. This model was never put on the market. There were other inventors after Aves, but it appears that Duke Elder developed the first progressive lenses marketed in 1922. These were made from aspherical surfaces. In 1955, Irving Rips at Younger Optics produced a blended lens: the Younger Seamless Bifocal.

In 1959, the first lenses of modern design, the Varilux & Carl Zeiss lenses, were developed by Bernard Maitenaz. Predictably, these early lenses were of rather crude design and much head tilting was still required. Soon, however, asymmetrical lenses were developed to aid comfort and vision. Computer technology has helped in perfecting progressive lenses, allowing for greater precision to aid each patient. Other advantages of progressive adjustment lenses

(PALs), are that they always offer some place in the glasses to give the correct focus for whatever one wants to see. They are typically easier for most people to adjust to because there is no line between lens areas. However, one must move one's head from side to side when reading. Cost is another problem with progressive lenses; they are double the cost of bifocals.

Another option is bifocal or progressive contact lenses. Although bifocal contact lenses were invented in 1938, the first practical models were not available until the late 1980s, and rapid development took place in the 1990s. Improvements have continued, and now

a number of models address different needs and requirements. Ease of use and comfort has also kept pace with the new designs.

 Letocha, Charles E. 1990. "The Invention and Early Manufacture of Bifocals." *Survey of Ophthalmology* 35, no. 3: 226–35.

Primary Document: Benjamin Franklin's Letter Describing His Invention of Bifocals (1725)

In May 1725, Benjamin Franklin wrote a letter to George Whatley describing his invention of bifocals, or what he called "double spectacles." He wrote that he particularly enjoyed being able to see the food he was eating and the facial expressions of the people with whom he dined. The letter, an excerpt of which is reproduced here, also contained a sketch of the bifocals.

I therefore had formerly two Pair of Spectacles, which I shifted occasionally, as in travelling I sometimes read, and often wanted to regard the Prospects. Finding this Change troublesome, and not always

sufficiently ready, I had the Glasses cut, and half of each kind associated in the same Circle, thus, the same convexity of glass, through which a man sees clearest and best at the distance proper for reading, is not the best for greater distances. By this means, as I wear my spectacles constantly, I have only to move my eyes up or down, as I want to see distinctly far or near, the proper glasses being always ready.

Bushnell, David (1740–c. 1824)

In 1775, David Bushnell, a Yale University student, had an idea for a submersible craft as a way to fight British ships attacking the United States during the American Revolution. The *Turtle*, called that because of its appearance, was powered by screw propellers and stayed submerged by using water as ballast—two more Bushnell discoveries. Able to approach enemy ships undetected, the *Turtle* would attach a time bomb to the hull and flee to safety.

But stealth and lethality were just two of the challenges Bushnell faced in building the *Turtle*. For example, what kind of materials would be used in constructing the hull? Since this was the 18th century, wood secured by iron hoops was the obvious choice. But how would the operator see? And, just as important,

how would he breathe? Bushnell solved the light problem by adding six small windows to the hatch. He dealt with the air problem by attaching two snorkels that closed when the craft was submerged. Because the air inside the submarine was limited by its size, the vessel was designed to travel on the surface or with its hatch and windows above water.

Operating the *Turtle* required more physical strength and stamina than David Bushnell possessed, so Continental Army sergeant Ezra Lee was at the controls when the submarine slipped into New York Harbor in September 1776 to attack British vessels. Lee tried to drill holes in one man-of-war but failed because the ship was lined with copper to ward off parasites that could damage her wooden hulls. Lee had to break off the attack. It would turn out to be the *Turtle's* only combat mission; it was lost the following

month when British frigates sank the tender ship that was trying to transport it out of the area. While it was recovered, it was never used again. Today, anyone wanting to see what the *Turtle* looked like has to settle for the full-size model on display at the U.S. Navy Submarine Force Library and Museum in Groton, Connecticut.

As for David Bushnell, he fought the rest of the Revolutionary War from land. He attempted to sink British ships with floating explosive mines and met with partial success, although a few of the mines detonated prematurely, killing innocent bystanders. In 1778, General George Washington proposed the formation of a unit specializing in sabotage, and Bushnell was placed in command. However, the British took

him prisoner in 1779. He was released in 1781, and his unit joined the Continental Army laying siege to Yorktown. After the Revolution, he left the army and settled in Georgia, where he taught school and practiced medicine. He died in Warrenton, Georgia, in about 1824.

Colden, Jane (1724–1766)

The first female botanist in America, Jane Colden learned science from her father's father, Cadwallader Colden, who had a hobbyist interest in botany and trained her in the Linnaean system of botanical classification. She studied flora in New York City, mainly along the Hudson River Valley. She was a well-known botanist in her time and was accepted among male botanists.

Jane Colden was born in the province of New York to Cadwallader and Alice (Christy) Colden. She was the fifth of 10 children. When her father learned of her interest in botany, he wrote to a friend, “As it is not usual for woemen [sic] to take pleasure in Botany as a Science I shall do what I can to incourage [sic] her in this amusement which fills up her idle hours to much better purpose tha[n] the usual amusements eagerly pursued by others of her sex” (Beck-Kaplan 2010, 36). This attitude was common at the time. Science was considered a suitable course of study for women because people thought it was unchanging and thus taught obedience to order. Women were particularly encouraged to study botany and astronomy, while men were encouraged to study the classics or law. Maria Mitchell, for example, was the most famed and esteemed astronomer of the pre-Civil War (1861–1865) period but lost some ground after the war as society came to believe that science should be a male-centered field of study. Science books in the 1700s were directed specifically toward women and emphasized that science was an undertaking that could improve the female mind and was preferable to other ways that women could spend their time. The growing popularity of novel reading as a leisure activity for women as well as the increasing affordability of books also led to more scientific books being geared toward women, such as the 1865 *The Young Lady's Geography*.

By 1757, Colden had described and sketched more than 300 local plants. She was known by her contemporaries as an expert botanist regarding species indigenous to New York and her surrounding area. She was also an expert in the Linnaean system of botanical classification. It is apparent from her writings and the writings of her peers that not only was she respected,

but she was also secure in her place as a botanist. If her observations differed from other work in the field, she did not hesitate to say so in her writings. Nonetheless, her father often received the praise and acclaim that should have been directed toward Colden. One example is when Carl Linnaeus, the creator of the Linnaean system, honored Cadwallader Colden, not his daughter, with the new generic plant name *Coldenia*.

During her time working as a botanist, Colden became a skillful plant illustrator and developed a technique for making ink impressions of leaves. She compiled information and illustrations for around 340 plants around the Hudson River Valley. She also joined the Natural History Circle, whose members consisted of both American and European botanists who shared seeds and plant samples with each other. In 1756 she discovered the gardenia, which she named after botanist Alexander Garden. The scientific name was later changed because another plant had been assigned the scientific name *Gardenia*, but the group of flowering plants that Colden identified is still informally called gardenia.

Colden's scientific curiosity in her professional life also showed through to her domestic life. In 1756 she maintained a log of her cheese making. The way that she recorded her efforts here reads much more like a book of experiments than a book of recipes. Colden married Dr. William Farquhar, a physician, on March 12, 1759. The marriage was short-lived because of her death in 1766. Like many women of her time, Colden died during the birth of their first child, who died within the week as well.

After Colden's death and during the American Revolutionary War, a Hessian captain found her drawings and plant descriptions. He returned to England with them, and now they are held at the British Museum. In 1963, the American Garden Clubs published part of the manuscript. Colden's unnamed manuscript is still prized today for its artistry and accuracy.

Daylight Saving Time

Even though Daylight Saving Time (DST) has been in use for the past century, it was conceived by ancient civilizations that adjusted their daily schedules to the sun's schedule. For example, Roman water clocks used different scales for different months of the year. American inventor and statesman Benjamin Franklin was the first to formally propose DST to save energy and make better use of daylight. He wrote an essay titled "The economical project for diminishing the cost of light" to the editor of the *Journal of Paris* in 1794, where he suggested that Parisians could economize on candle usage by getting out of bed earlier, making use of the morning light instead.

Franklin calculated that using seven hours of candlelight for 183 nights between March 20 and September 20 equaled 1,281 hours for a half year of candle usage. Multiplying by 100,000 Parisian families gave 128,100,000 hours by candlelight. 64,050 pounds of tallow and wax were required, since each candle required a half pound of them. He calculated the total cost of burning a candle to be 96,075,000 *livres tournois*, "an immense sum that the city of Paris might save every year." Hence, Franklin proposed regulations such as levying a tax on every window built with shutters to keep out the light of the sun, rationing candles to one pound per family per week, and having the regulation enforced by constabulary. Guards were to be posted to stop the passage of all coaches upon the streets after sunset except those of physicians, surgeons, and midwives. He further suggested that at dawn, church bells, and, if necessary, cannon should inform the citizenry of the advent of light: "Oblige a man to rise at four in the morning, and it is possible he will go willingly to bed at eight in the evening."

The idea of DST was popularized much later—during World War I, when nations aimed to conserve energy and minimize the use of artificial lighting to save fuel for the war effort. Germany was the first country to introduce DST, when clocks were turned one hour ahead on April 30, 1916. The idea was quickly accepted by the United Kingdom, followed by France. In the United States, DST was first introduced in 1918 when President Woodrow Wilson signed it into law. It was repealed seven months later but reinstituted during World War II (between February 9, 1942, and September 30, 1945), in the United States and Canada. The United Kingdom applied "Double Summer Time" during this period by setting clocks two hours ahead of GMT during summer and one hour ahead of GMT during the winter.

Between 1945 and 1966, there were no uniform rules for DST in the United States, and this caused widespread confusion, especially for trains, buses, and the broadcasting industry. Consequently, Congress established the Uniform Time Act of 1966, which stated that DST would begin on the last Sunday of April and end on the last Sunday of October. During the energy crisis of the early 1970s, Congress extended DST to a period of 10 months in 1974 and 8 months in 1975, saving the equivalent of 10,000 barrels of oil each day, but the program remained controversial. Between 1987 and 2006, the United States observed about seven months of DST each year. The current eight-month schedule was introduced in 2007 and follows the Energy Policy Act of 2005. Now DST starts on the second Sunday in March and ends on the first Sunday in November.

DST is now in use in over 70 countries and affects over a billion people every year. The beginning and end dates vary from country to country. In 1996, the European Union (EU) standardized an EU-wide DST schedule, which runs from the last Sunday in March to the last Sunday in October.

Extension Arm (Long Arm)

Benjamin Franklin invented the extension or long arm in 1786 when he was 80 years old. After his final trip abroad, returning to Philadelphia in 1785 after serving as the U.S. minister to France, he had accumulated a large collection of books in his home library. Earlier, in 1731, he had composed the charter for the Library Company of Philadelphia.

Franklin liked to spend time with books and particularly enjoyed the Philadelphia library, but reaching books on high shelves continued to be a challenge, particularly during his later years. Hence, he devised a simple extension arm or “long arm.” The device had a grasping claw consisting of two “fingers” that were attached at the end of a long piece of wood or pipe. These fingers could be opened or closed by pulling on a cord. This tool allowed Franklin to retrieve books located three to four feet higher than he was normally able to reach.

Franklin wrote about the tool to his nephew John Williams in a letter dated February 12, 1786, in which he noted the practical utility of his latest invention.

This was a simple, clever yet resourceful tool that could be used for fetching not only books but other objects as well. Derivatives of this concept are still used today. This is very similar to the “grabber” arm that is common today for both in-home and outdoor use. Modern incarnations of the extension arm are helpful in bringing down high-placed items, particularly in supermarkets and in homes, where they are often used by older persons. Extension arms called “trash grabbers” are handy for use in outdoor settings, allowing the user to pick up trash without bending over again and again. Few modern users know that they can thank Benjamin Franklin for this handy tool.

Fire Safety

While the notion of fire safety spans all the way back to the Roman Empire after the Great Fire of Rome in 64 CE, modern American fire safety did not exist until 1631, when John Winthrop established a building code to outlaw thatched roofs and wooden chimneys. This was the first means of fire prevention, one of several key areas of fire safety, and was expanded in 1648 to allow for fire wardens, who would inspect buildings and could issue fines to homeowners for negligence. However, paid firefighters did not come about until nearly 30 years later, after a major fire in Boston.

The First Union Fire Company, established by Ben Franklin in 1736, was the first volunteer fire department. It was not until the Great Chicago Fire (1871), the Great Peshtigo Fire (1871), and the Great Boston Fire (1872) happened in rapid succession that major changes to the fire codes and other fire safety developments occurred.

After these three major fires, a sprinkler system, which had been originally designed in 1812, was built upon by Henry S. Parmalee to be automatic. Joseph Grinnell further developed this system until eventually, in 1890, the glass disk sprinkler head had been created, a system that is still used today. At the turn of the 20th century, the most deadly theater fire in American history occurred at the Iroquois Theater in Chicago. After the tragedy, the federal government created requirements for exit pathways, door size, and exit sign markings, plus maximum occupancy laws. A fire in Baltimore in 1904 led to the creation of a national standard for fire hose sizes, and the General Slocum Water Boat Fire in New York caused an improvement on safety equipment after 1,030 people died when archaic and degrading equipment failed.

Perhaps the most influential fire, the Triangle Shirtwaist Factory Fire in 1911, established the need for fire exits from buildings several stories high after many women jumped from buildings to escape danger. Fires in the 1940s resulted in a refinement of the safety codes to include revolving doors, a standard for the number of fire exits in a building, fire-resistant exit structures, and the development of a fire alarm. In 1958, a school fire caused the implementation of school regulations to protect students. When firefighters in Los Angeles noted that the spread of fire was rapid when wind speeds were high, shingled roofs became a requirement.

In 1967, a major fire claimed the lives of three Apollo 1 astronauts. The tragedy resulted in preemptive increased safety standards for commercial airplanes. The next major breakthrough in fire safety was in 1980, after the MGM Hotel caught fire in Las Vegas. This fire brought about the discovery that smoke can kill just as easily as fire itself can. In the following decades, smoke detectors have become a more common requirement, with CO₂ often being integrated into a smoke alarm as well. Improved fire safety codes are aimed at reducing loss of life due to lack of foresight in building construction.

Flexible Catheter

Benjamin Franklin invented the flexible catheter in 1752. Prior to his invention, catheters were hard tubes jammed into the bladder through the urethra, primarily rigid (and painful) metal ones. His invention was precipitated by the fact that one of his older brothers, John, suffered from kidney stones and had to undergo an excruciating daily ritual of using a bulky metal catheter.

John wrote to Franklin from Boston, complaining about problems with urinating due to bladder stones. Franklin wrote back that he had an idea for a flexible catheter and how one might be made. He further informed John that he had given his directions to a silversmith, who made a model for him.

A follow-up letter from Franklin to his brother in January 1753 suggests that John did show some

near-term improvement by injecting liquids containing lye through the flexible catheter to dissolve the stones. Franklin wrote back to John, saying that he was happy to be informed that he was better. John lived for an additional four years after receiving the new catheter.

Franklin's flexible catheter was a much more practical and less painful solution than the rigid tube that doctors had been using. It was made from silver wire coiled with joints to allow the flexibility of hinged metal segments. Franklin himself later needed the flexible catheters, as he suffered from episodes of gout and eventually complained of urinary difficulties that were probably due to a uric acid bladder stone.

This type of catheter was a major improvement on existing ones. Aulus Celsus, a Roman encyclopedist living in the first century, mentioned in his *De Medecina* that bronze catheters had been found in the rubble of Pompeii. Catheters were made of metal until the 11th century and were difficult to insert, hence extremely uncomfortable. Avicenna (980–1037) described the first primitive flexible catheters, which were made of animal skins treated with agents to make them firm enough for insertion after lubrication. Fabricus ab Acquapendente, who lived in Italy in the early 17th century, used a horn that would soften when left in place, as well as a tube of cloth impregnated with wax. Yet these innovations were not very satisfactory.

In the late 1600s, a Dutch surgeon named van Solingen made a flexible catheter of wound silver wire that was covered with soft animal skin and treated with wax. Early in the 18th century, Francesco Roncalli Parolino made further advancements in building a flexible catheter by covering a fine, thin spiral tube with fine skin and later silk. Franklin did not mention any of these European devices or their inventors in his writings, and so it is difficult to ascertain how much they influenced his innovation. Yet he is the one who had introduced the most modern of flexible catheters (until then) in the American colonies.

Much more advanced versions of the flexible catheter are used today. Although it wasn't the most sophisticated device that Franklin invented, it was very popular in America at that time and was a welcome relief for hundreds of people with bladder problems.

Food Production, Native American

In North America prior to European contact, Native American women held equal status with men, because gender-specific occupational roles gave women control over food and vital resources. Native American societies varied in organization, language, belief systems, and cultural practices. However, most of these hunter-gather and hunter-agricultural societies practiced what anthropologists call "gender complementarity": women and men complemented each other by doing different jobs, thereby enabling the group as a whole to find and process the most available food.

In many cultures, women gathered wild plant foods: leafy plants, seaweed, berries, roots, nuts, and seeds. Successful gathering required botanical knowledge of plant location, the best collection period, and specific preparation. Mothers and female relatives began teaching girls gender-specific knowledge when they reached eight years old. Girls learned plant identification and processing: baking and drying roots and drying and grinding grains. Once dried, food staples could be stored and reconstituted in a stew or porridge

or baked as a cake or bread. Meat and other vegetables were added to these staples.

Some resources, such as acorns, required skilled preparation to make them safe for eating. The camas bulb, gathered on the northwestern plateau, required expertise to distinguish edible from poisonous bulbs. Among these people, young girls demonstrated advancement into womanhood by successfully collecting edible camas and preparing it for tribal elders, a ceremonial equivalent to a boy's first hunt. Sacagawea's knowledge of camas and other roots saved the Lewis and Clark Expedition from deprivation.

Women made tools for their own horticultural use. Digging sticks served to unearth wild roots and plant seeds. Storing and processing food required containers; therefore, girls learned basketry, pottery, and leather working.

Women originated farming technology and typically grew agricultural crops. Gourds, sunflowers, and goosefoot or quinoa were North American crop plants. Women in Mexico and Central America developed melons, chilies, squash, beans, and maize. Prior to European arrival, these crops were grown by peoples from the Anasazi and Pueblo cultures of the Southwest to the Iroquois Confederacy in the Northeast. Food surpluses produced by women increased native populations and enabled semipermanent villages and large civic complexes. The women who produced these foods held high or equivalent social positions with men, who provided large-game protein.

The Iroquois identified maize, beans, and squash as distinctively feminine icons known as the "Three Sisters." Eaten together, these staples provided a nutritionally well-balanced diet. The three plants also nurtured each other: the squash shaded the maize's roots, the maize provided a stalk for the beans to climb, and the beans replenished the soil with nitrogen for its sisters.

Women developed maize into a high-yield crop essential to community well-being. Many cultures integrated maize into their religions, celebrating planting and/or harvesting in the Green Corn Ceremony. The Corn Mother and other feminine spirits honored fertility, regeneration, and the vital role of women. In most cultures, women managed agricultural lands and transferred farming or gathering rights through matrilineal descent (from mother to daughter).

Native Americans grill and roast fish and boil meat with hominy, while a couple sits on a mat, eating from a plate between them. (Florilegius/SSPL/Getty Images)

Women controlled their harvest and in many cultures could barter or sell any excess food they produced. In addition, the tools and containers a woman made were her individual property. Food production provided women with independent economic power within their communities. Contrary to the views of Europeans who documented encounters with native peoples, Native American women were not performing drudgery work for their husbands; they were managing their own agricultural enterprises. Male occupations included hunting large game and fishing, but women frequently captured small game—voles, prairie dogs, and rabbits—in plant fiber nets or snares. Gender roles did not bar a skilled woman from hunting. Some women's graves within mound-building cultures have been found to contain personal hunting paraphernalia: stone balancing weights for a spear-tossing implement called

an "atlatl." Similarly, a man could act in a female role. Female and male genders complemented each other, and therefore both were valued.

Men hunted caribou, bison, and deer, while women typically processed the carcasses—skinning them, cutting up the flesh, and drying or smoking the meat. Prey such as salmon and bison were harvested in vast quantities in short bursts of time. In such situations, community members worked together to secure the greatest resource abundance. Women with expertise fished, and men assisted women in smoking salmon and butchering bison. Women did not prepare or process food during their menstrual cycles. Menses was a time of spiritual introspection; other family members then handled that woman's everyday tasks.

Among the Iroquois, the clan mother made sure that clan members (extended matrilineal relatives)

received enough food. Even in cultures where women did not butcher meat, they typically distributed meat resources. Control over food gave women social and economic power. Among the Senecas of the Iroquois Confederacy, women provisioned warriors. They could not stop male warfare, but they could refuse to provide food supplies, effectively curtailing a war party.

Management of food resources yielded personal autonomy. Women who controlled their own resources were independent and usually free to divorce. Some female English captives, such as Mary Jemison, stayed within Native American societies because they experienced greater personal autonomy there.

When Europeans influenced Native American men to become farmers or imposed food resources on native societies, they changed the economic status of women within these societies. Without control over food resources, women's political power diminished. The social imbalance created by the loss of complementarity was destructive to Native American societies and caused a decline in female social status within tribal cultures through the 20th century.

Franklin, Benjamin (1706–1790)

He was never president of the United States, but Benjamin Franklin influenced the transformation of 13 separate colonies to a new nation. He is remembered as a statesman, writer, and inventor. He was the only Founding Father to sign the Declaration of Independence (1776), the Treaty of Alliance with France (1778),

the Treaty of Paris (1783), and the United States Constitution (1787).

Franklin was born in 1706 in Boston, Massachusetts. His father, Josiah Franklin (1657–1745) was a soap maker and candle maker. Abiah Folger (who died in 1744) was his mother. He attended Boston Latin School for two years. When he was 10 years old, he left school to work for his father.

Franklin's brother, James, was nine years older than he was and worked as a printer. When Franklin was 12, he was apprenticed to James. James founded the weekly newspaper *The New England Courant* in 1721. Franklin submitted letters to the *Courant*, but James refused to print them. Franklin changed his handwriting and using the pen name "Silence Dogood" to submit humorous letters written by a fictional middle-aged widow. The letters were very popular.

James was arrested in 1722 for publishing unflattering remarks about the governor and was jailed, without trial, for three weeks, during which time Franklin ran the newspaper. Franklin and James's relationship was strained, and Franklin left the apprenticeship without his brother's permission.

Franklin left Boston and went to Philadelphia when he was 17. He worked in print shops to support himself. There, Franklin met Deborah Read (c. 1708–1774). He planned to go to London so he proposed to her, but her mother refused the match. Franklin sailed to London and worked as a printer. Deborah's mother convinced her to marry another man—who deserted her a few months after they were married.

Franklin returned to Philadelphia in 1726. Since Deborah was unable to marry him, she became Franklin's common-law wife in 1730. They remained together until her death in 1774 and had two children: Francis (1732–1736) and Sarah "Sally" (1743–1808). The couple also raised Franklin's illegitimate son, William (1730–1813).

Franklin formed a group of tradesmen and artisans who met to discuss topics of the day and books. This "junto" group, as he called it, began in 1727. Books were expensive and hard to get, so the members combined their books and borrowed them from each other. This idea developed into pooling members' money to buy books for the group's borrowing. This idea of a lending library led to the Library Company of Philadelphia being founded in 1731.

Franklin published the first *Poor Richard's Almanack* in late 1732 using the pen name Richard Saunders. Saunders and his wife, Alice Addertongue, offered folksy humor and poked fun at pretentious snobs as well as everyday people. It also contained proverbs and sayings. Franklin wrote for the *Almanack* for 25 years.

Franklin organized one of the first volunteer fire departments in America: the Union Fire Company was formed in 1736.

Franklin was always curious and developed a variety of innovations. He invented a mechanical arm to retrieve books from high shelves (and also replace them). Among his many inventions were bifocal glasses (each lens has two optical powers) and the Franklin stove (it had a metal liner that produced more heat and less smoke).

He experimented with electricity. His experiments led to the invention of the lightning rod in 1750. It was an iron rod that was attached at the top of a structure; a wire ran from the rod to the ground. If lightning struck the rod, the electricity would go down it and then the wire, to be dispersed in the ground. His work with electricity earned him honorary degrees from Harvard and Yale in 1753.

Franklin's political career began in 1748, when he served as a Philadelphia councilman. He then served as a justice of the peace and in 1751 was elected to the Pennsylvania Assembly. He helped organize the Pennsylvania Militia in 1756.

The Pennsylvania Assembly sent Franklin to London in 1757 as colonial agent to represent the colony's interests. He didn't return to Philadelphia until 1763.

Franklin remained influential in Pennsylvania politics. The Assembly chose him as one of its delegates to the Second Continental Congress in 1775. He was

one of five delegates selected to help draft the Declaration of Independence.

Franklin was chosen as commissioner for the United States to France in 1776. He negotiated the Treaty of Paris, which ended the Revolutionary War in 1783. Though never president of the United States, in 1785, he did become president of Pennsylvania, a post equivalent to governor. He served several terms. He also served as a delegate to the Constitutional Convention held in Philadelphia in 1787.

Franklin's health declined as he aged. He suffered from obesity and gout for many years and died in 1790 in Philadelphia.

To say that Franklin was a man of many talents would be an understatement. Most people would be happy to have achieved even one of his accomplishments. Benjamin Franklin is remembered for his wit, his imagination, his inventions, and as a founder of the United States of America.

Primary Document: Letter of Benjamin Franklin Describing His Experiments with Electricity (c. 1750)

In 1751, the Royal Society arranged for the publication of a series of letters from Benjamin Franklin, written between 1747 and 1750, describing his experiments with electricity. Franklin demonstrated his new theory of positive and negative charges, suggested the electrical nature of lightning, and proposed a tall, grounded rod as a protection against lightning. The following are excerpts from a letter in

which Franklin describes his efforts to electrocute a turkey.

I have lately made an Experiment in Electricity that I desire never to repeat. Two nights ago, being about to kill a turkey by Shock from two large glass Jars containing as much electrical fire as forty common Phials, I inadvertently took the whole thro' my

own Arms and body. . . . The Company present (whose talking to me and to on another I suppose occasioned my Inattention to what I was about) say that the flash was very great and the crack as loud as a pistol; yet my Senses being instantly gone, I neither Saw the one nor heard the other; nor did I feel the Stroke on my hand, tho' I afterwards found it raised a round swelling where the fire entere'd as big as a half a Pistol Bullett by which you may judge the Quickness of Electrical Fire. . . .

I then felt what I know not how well to describe; as universal Blow thro'out my whole Body from head to foot which seem'd within as well as without; after which the first thing I took notice of was a violent quick Shaking of my body which gradually remitting, my sense as gradually return'd, and then I tho't the

Bottles must be discharged but Could not conceive how, till att last I Perceived the Chain in my hand, and Recollected what I had been About to do: that part of my hand and fingers which held the Chain was left white as tho' the Blood had been Driven Out, and Remained so 8 or 10 Minutes After, feeling like Dead flesh, and I had a Numbness in my Arms and the back of my Neck, which Continued till the Next Morning but wore off. Nothing Remains now of this Shock but a Soreness in my breast Bone, which feels As if it had been Bruised. I Did not fall, but Suppose I should have been Knocked Down if I had Received the Stroke in my head: the whole was Over in less than a minute.

Franklin Stove

The Franklin stove was invented by Benjamin Franklin in 1742. It was a metal-lined fireplace that was situated in the center of a room. This wood-burning stove provided more heat with less fuel and hence less smoke. Its cast-iron furnace was designed to radiate heat from the middle of the room in all directions, while the iron walls absorbed heat, providing warmth to the room much longer after the fire went out. Such fireplaces helped save wood and were used in many houses in Pennsylvania as well as in other neighboring colonies. It was also called the "circulating stove" or the "Pennsylvania fireplace."

Franklin's design idea for the stove that provided more heat and less smoke was based on two books by Jean Théophile Desaguliers (1683–1744), a French immigrant to England. He also incorporated new scientific concepts about heat developed by the Dutch physician Herman Boerhaave (1688–1738), a proponent of Isaac Newton's ideas. The stove was approximately 30 inches tall with a box shape. The front side was open except for a decorative panel in the upper part of the box. The back of the box was placed a few inches away from the flue or chimney. These panels were bolted together with iron screws through precast ears. The smoke was forced into the holes through small, thin rectangular prisms inside the panels.

The two key features of the Franklin stove were: (a) a hollow baffle or a metal panel that directed the flow of the fire's fumes downward, and (b) a flue that acted as an inverted siphon. Franklin called the inverted siphon an "aerial syphon" or "syphon reversed." Cool air entered the baffle through a duct under the floor, while smoke exited through a U-shaped duct in the floor. The hollow baffle was positioned inside and near the rear of the stove. It performed two critical functions: it lengthened the path that the fire's fumes had to follow before reaching the chimney, allowing more heat to be extracted from the fumes, and the duct placed near the fire helped heat the room's air via convection.

Franklin initially presented a model of the stove to a friend, Robert Grace, and tried to promote it with a pamphlet called *An Account of the New Invented Pennsylvanian Fire-Places*, in which he explained the construction and manner of operation of the stove and why it was the best method for warming rooms. The deputy governor of Pennsylvania, George Thomas, offered Franklin the patent of this design and invention, but he refused because he believed that "as we enjoy great advantages and inventions of others, we should be glad of an opportunity to serve others by any invention of ours, and this we should do freely and generously."

Hence, several others were able to use his design and improve it. An ironmonger in London followed

the instructions from the pamphlet, made minor adaptations to the machine, and patented it in England. When Franklin was in London to represent the colonies during the American Revolution, he was approached by Filippo Mazzei, an Italian businessman looking to buy a proper Franklin stove. It was then that Franklin discovered how many variations of his stove existed. The experience formed a friendship that aided the Colonies further. Mazzei became America's representative in Europe, soliciting funds and support for the war against Britain.

Even though the original goal of the stove was for the dual purpose of cooking and heating a room, over time, the Franklin stove was primarily used for heating. After some initial enthusiasm, the stove's sales tapered off. The primary problem was with the inverted siphon—the smoke had to pass through a cold flue set in the floor before it could enter the chimney; hence, the stove did not have a good draft since the smoke cooled too much. The inverted siphon operated properly only when the fire burned constantly so that the temperature in the flue was high enough to produce a draft. David Rittenhouse later designed a much-improved version that eliminated

several of the problems in Franklin's stove, and it also became popular. Yet, Franklin's version is better remembered because of its pioneering features. Even today, most wood-burning stoves in the United States are box-shaped like the original Franklin stove.

Primary Document: Excerpt from Benjamin Franklin's *An Account of the New Invented Pennsylvanian Fire-Places* (1744)

Benjamin Franklin published An Account of the New Invented Pennsylvanian Fire-Places in 1744 to describe a new kind of heating system. In the excerpt here, he explains how fireplaces work as well as common types of fireplaces and their deficiencies.

IN these Northern Colonies the Inhabitants keep FIRES to sit by, generally *Seven Months* in the Year; that is, from the Beginning of October to the End of April; and in some Winters near *Eight Months*, by taking in part of September and May.

WOOD, our common Fewel, which within these 100 Years might be had at every Man's Door, must now be fetch'd near 100 Miles to some Towns, and makes a very considerable Article in the Expence of Families.

As therefore so much of the Comfort and Conveniency of our Lives, for so great a Part of the Year, depends on the Article of FIRE; since Fuel is become so expensive, and (as the Country is more clear'd and settled) will of course grow scarcer and

dearer; any new Proposal for Saving the Wood, and for lessening the Charge and augmenting the Benefit of FIRE, by some particular Method of Making and Managing it, may at least be thought worth Consideration.

THE NEW FIRE-PLACES are a late Invention to that purpose (experienced now three Winters by a great Number of Families in Pennsylvania) of which this Paper is intended to give a particular Account.

THAT the Reader may the better judge whether this Method of Managing Fire has any Advantage over those heretofore in Use, it may be proper to consider both the old and new Methods separately and particularly, and afterwards make the Comparison.

IN order to this, 'tis necessary to understand well some few of the Properties of AIR and FIRE, viz.

1. AIR is rarified by *Heat*, and condens'd by *Cold*; i.e. the same Quantity of Air takes up more Space when warm than when cold. This may be

shown by several very easy Experiments. Take any clear Glass Bottle (a Florence Flask stript of the Straw is best) place it before the Fire, and as the Air within is warm'd and rarified, part of it will be driven out of the Bottle; turn it up, place its Mouth in a Vessel of Water, and remove it from the Fire; then, as the Air within cools and contracts, you will see the Water rise in the Neck of the Bottle, supplying the Place of just so much Air as was driven out. Hold a large hot Coal near the Side of the Bottle, and as the Air within feels the Heat, it will again distend and force out the Water. Or, Fill a Bladder half-full of Air, tie the Neck tight, and lay it before a Fire as near as may be without scorching the Bladder; as the Air within heats, you will perceive it to swell and fill the Bladder, till it becomes tight as if full-blown: Remove it to a cool Place, and you will see it fall gradually, till it become as lank as at first.

2. AIR rarified and distended by Heat, is specifically lighter than it was before, and will rise in other Air of greater Density. As Wood, Oil, or any other Matter specifically lighter than Water, if plac'd at the Bottom of a Vessel of Water, will rise till it comes to the Top; so rarified Air will rise in common Air, till it either comes to Air of equal Weight, or is by Cold reduc'd to its former Density.

A FIRE then being made in any Chimney, the Air over the Fire is rarified by the Heat, becomes lighter and therefore immediately rises in the Funnel and goes out; the other Air in the Room (flowing towards the Chimney) supplies its Place, is rarified in its turn, and rises likewise; the Place of the Air thus carried out of the Room is supplied by fresh Air coming in thro' Doors and Windows, or, if they be shut, thro' every Crevice with Violence, as may be seen by holding a Candle to a Keyhole: If the Room be so tight as that all the Crevices together will not supply so much Air as is continually carried off, then in a little time the Current up the Funnel must flag, and the Smoke being no longer driven up must come into the Room.

1. FIRE throws out Light, Heat, and Smoke (or Fume). The two first move in right Lines and with great Swiftmess; the latter is but just separated from the Fuel, and then moves only as it is carried by the Stream of rarified Air. And

without a continual Accession and Recession of Air to carry off the Smoaky Fumes, they would remain crouded about the Fire, and stifle it.

2. HEAT may be separated from the Smoke as well as from the Light, by means of a Plate of Iron, which will suffer Heat to pass through it without the others.
3. FIRE sends out its Rays of Heat, as well as Rays of Light, equally every way: But the greatest sensible Heat is over the Fire, where there is, besides the Rays of Heat shot upwards, a continual rising Stream of hot Air, heated by the Rays shot round on every Side.

THESE Things being understood, we proceed to consider the Fire-places heretofore in Use, viz.

1. The large open Fire-places used in the Days of our Fathers, and still generally in the Country, and in Kitchens.
2. The newer-fashion'd Fire-places, with low Breasts, and narrow Hearths.
3. Fire-places with hollow Backs, Hearths and Jams of Iron, (described by Mons. Gauger) for warming the Air as it comes into the Room.
4. The Holland Stoves, with Iron Doors opening into the Room.
5. The German Stoves, which have no Opening in the Room where they are us'd, but the Fire is put in from some other Room, or from without.
6. Iron Pots, with open Charcoal Fires, plac'd in the middle of a Room.
1. The first of these Methods has generally the Conveniency of two warm Seats, one in each Corner; but they are sometimes too hot to abide in, and at other times incommoded with the Smoke; there is likewise good Room for the Cook to move, to hang on Pots, &c. Their Inconveniencies are, that they almost always smoke if the Door be not left open; that they require a large Funnel, and a large Funnel carries off a great Quantity of Air, which occasions what is called a strong Draft to the Chimney; without which strong Draft the Smoke would come out of some Part or other of so large an Opening, so that the Door can seldom be shut; and the cold Air so nips the Backs and Heels of those that sit before the Fire, that they have no Comfort, 'till either Screens or Settles are provided

(at a considerable Expence) to keep it off, which both cumber the Room and darken the Fireside. A moderate Quantity of Wood on the Fire in so large a Hearth, seems but little; and, in so strong and cold a Draught, warms but little; so that People are continually laying on more. In short, 'tis next to impossible to warm a Room with such a Fire-place: And I suppose our Ancestors never thought of warming Rooms to sit in; all they purpos'd was to have a Place to make a Fire in, by which they might warm themselves when acold.

2. MOST of these old-fashion'd Chimneys in Towns and Cities, have been, of late Years, reduc'd to the second Sort mention'd, by building Jambs within them, narrowing the Hearth, and making a low Arch or Breast. 'Tis strange, methinks, that tho' Chimneys have been so long in Use, their Construction should be so little understood till lately, that no Workman pretended to make one which should always carry off all the Smoke, but a Chimney-cloth was look'd upon as essential to a Chimney: This Improvement, however, by small Openings and low Breasts, has been made in our Days; and Success in the first Experiments has brought it into general Use in Cities, so that almost all new Chimneys are now made of that sort, and much fewer Bricks will make a Stack of Chimneys now than formerly. An Improvement so lately made, may give us Room to believe that still farther Improvements may be found, to remedy the Inconveniencies yet remaining. For these new Chimneys, tho' they keep Rooms generally free from Smoke, and, the Opening being contracted, will allow the Door to be shut, yet the Funnel still requiring a considerable Quantity of Air, it rushes in at every Crevice so strongly, as to make a continual Whistling or Howling; and 'tis very uncomfortable as well as dangerous to sit against any such Crevice. Many Colds are caught from this Cause only; it being

safer to sit in the open Street; for then the Pores do all close together, and the Air does not strike so sharply against any particular Part. The Spaniards have a Proverbial Saying, *If the Wind blows on you thro' a Hole, Make your Will, and take Care of your Soul*. Women, particularly, from this Cause, (as they sit much in the House) get Colds in the Head, Rheums and Defluctions, which fall into their Jaws and Gums, and have destroy'd early many a fine Set of Teeth in these Northern Colonies. Great and bright Fires do also very much contribute to damage the Eyes, dry and shrivel the Skin, and bring on early the Appearances of Old-Age. In short, many of the Diseases proceeding from Colds, as Fevers, Pleurisies, &c. fatal to very great Numbers of People, may be ascrib'd to strong-drawing Chimneys, whereby, in severe Weather, a Man is scorch'd before, while he's froze behind. In the mean time very little is done by these Chimneys towards warming the Room; for the Air round the Fire-place which is warm'd by the direct Rays from the Fire, does not continue in the Room, but is continually crouded and gather'd into the Chimney by the Current of cold Air coming behind it, and so is presently carried off.

In both these Sorts of Fire-places, the greatest Part of the Heat from the Fire is lost: For as Fire naturally darts Heat every way, the Back, the two Jambs, and the Hearth, drink up almost all that's given them, very little being reflected from Bodies so dark, porous and unpolish'd; and the upright Heat, which is by far the greatest, flies directly up the Chimney. Thus Five Sixths at least of the Heat (and consequently of the Fewel) is wasted, and contributes nothing towards warming the Room.

Glass Harmonica (Armonica)

Benjamin Franklin created the first glass harmonica in 1761. It was his favorite invention. It was a mechanized version of a popular entertainment in England in the

early 18th century made famous by Richard Pockridge (1690–1759) and Christoph Glück (1714–1787) that involved playing music on upright wine goblets, with tones made by rubbing one's fingers around the lips of glasses filled with different quantities of fluid.

In 1761, Franklin was in London, where he regularly attended concerts. One that he attended was by Deleval, a colleague of his in the Royal Academy, who performed on a set of water-tuned wineglasses patterned after Pockridge's instrument. Intrigued, Franklin began working on his invention, intending it to be more convenient to play than wine glasses. He initially called it the "glassychord" but soon settled on the name "armonica" in honor of the musical language of the Italians (after the Italian word for harmony: "armonia"), a fact that he explained in a letter to Italian natural philosopher and electrician Father Giambatista Beccaria (1716–1781).

Franklin worked with London glassblower Charles James in building his armonica. The instrument consisted of variously sized and tuned glass bowls that rotated on a common shaft and was played by touching the spinning bowls with wet fingers. The foot-treadle-operated instrument held 37 glass bowls. The bowl rims were color coded according to note; the C's were red, D's orange, E's yellow, etc.

It took several trials to construct the glass armonica. The glasses were hemispherical with an open neck or socket in the center so they could be fixed on an iron spindle. They were then arranged sequentially on the spindle, the largest at one end and graduating in size to the smallest at the other. The tones depended on the size of the glasses. The spindle was adjusted based on the principle of the common spinning wheel, fixed horizontally in a case, and turned by a wheel attached to its larger end. The performer sat in front of the instrument, and the tones were brought out by applying a wet finger to the exterior of the glasses as they turned around.

The instrument had its world premiere on February 17, 1762, in Spring Gardens, London, when an English musician, Marianne Davies (1743–1818), who had acquired great skill playing it the previous year, played along with her sister, Cecilia Davies, a classical soprano singer who also played the flute and harpsichord. The sisters also performed in front of large audiences in Dublin (1763), other venues in England, and in Europe, where Mozart heard them play. Marianne Davies regularly corresponded with Franklin after her initial concert and expressed her desire to play the armonica once again before her death.

Initially, two instruments were built—one for Franklin, which he later brought back to Philadelphia, and a second for Davies, who toured with it. They were then manufactured in London and sold to the public for 40 guineas each in the late 18th century.

The armonica was quite popular in Germany. Franz Mesmer used it as background music to "mesmerize" his patients. He introduced it to Mozart, who wrote two pieces for it (a solo armonica piece and a larger quintet for armonica, flute, oboe, viola, and cello). Beethoven also composed music for the glass armonica, and many of these musicians' colleagues composed for it as well—approximately 200 pieces for armonica (solo or with other instruments) survive from that era. Franklin himself liked playing Scottish tunes on his instrument for his guests during his eight and a half years in France as the United States' first ambassador between 1776 and 1785.

With the advent of the 19th century, musical preferences changed. Performances moved out of the small, aristocratic halls of Mozart's day into large public concert halls. There, without proper amplification, the armonica could not be heard. Other orchestra instruments such as strings, winds, and brass were all modified to increase their volume, but it was difficult to make the armonica louder. Concert reviews from that era lament the fact that the armonica sounded wonderful but had a problem being heard over other instruments. As such, it gradually lost popularity.

Primary Document: Excerpt of Benjamin Franklin's Letter to Father Giambattista Beccaria Describing the Glass Harmonica (1762)

In 1762, Benjamin Franklin wrote a letter to Father Beccaria, a philosopher at the University of Torino (Italy), about his "armonica." In later years, Franklin said that the glass armonica, with its bell-like tones, was the most satisfying invention of his life. He refused to take a patent out on his improved instrument, believing it belonged to humanity, not himself.

London,
July 13, 1762

Reverend Sir,

I once promised myself the pleasure of seeing you at Turin, but as that is not now likely to happen, being just about returning to my native country, America, I sit down to take leave of you (among others of my European friends that I cannot see) by writing . . .

Perhaps, however, it may be agreeable to you, as you live in a musical country, to have an account of the new instrument lately added here to the great number that charming science was before possessed of: As it is an instrument that seems peculiarly adapted to Italian music, especially that of the soft and plaintive kind, I will endeavour to give you such a description of it, and of the manner of constructing it, that you, or any one of your friends may be enabled to imitate it, if you incline so to do, without being at the expence and trouble of the many experiments I have made in endeavouring to bring it to its present perfection.

You have doubtless heard the sweet tone that is drawn from a drinking-glass, by passing a wet finger round its brim. One Mr. Pockeridge, a gentleman from Ireland, was the first who thought of playing tunes, formed of these tones. He collected a number

of glasses of different sizes, fixed near each other on a table, and tuned them by putting into them water, more or less as each note required. The tones were brought out by passing his finger round their brims. He was unfortunately burnt there, with his instrument, in a fire which consumed the house he lived in. Mr. E. Delaval, a most ingenious member of our Royal Society, made one in imitation of it, with a better choice and form of glasses, which was the first I saw or heard . . .

Being charmed by the sweetness of its tones, and the music he produced from it, I wished only to see the glasses disposed in a more convenient form, and brought together in a narrower compass, so as to admit of a greater number of tunes, and all within reach of hand to a person sitting before the instrument, which I accomplished, after various intermediate trials, and less commodious forms, both of glasses and construction, in the following manner . . .

The advantages of this instrument are, that its tones are incomparably sweet beyond those of any other; that they may be swelled and softened at pleasure by stronger or weaker pressures of the finger, and continued to any length; and that the instrument, being once well tuned, never again wants tuning.

In honour of your musical language, I have borrowed from it the name of the instrument, calling it the Armonica.

With great esteem and respect, I am, Etc.

B. Franklin

Glover, Elizabeth (d. 1643)

In 1638, Elizabeth Glover set up the first printing press in the Massachusetts Bay Colony's new university—present-day Harvard University.

Glover and her husband, Jose Glover, had sailed from their home in England with their five children and a team

of technicians to the English colonies. They brought a printing press with them to set up there. Glover's husband had originally intended the press to mass-produce religious texts. As a minister, his goal was to spread his religion in the colonies, and printing texts would allow most people, regardless of class, to own copies. But during the voyage to the colonies, Minister Glover passed away.

Upon arriving in Massachusetts, Elizabeth Glover went right to work setting up her printing shop. The first president of Harvard, Henry Dunster, took an interest in her business, and they married three years after she arrived. By that time, the press had already printed the infamous Bay Psalm Book. This book would have been considered crude in the modern day. It had 300 pages of text containing paraphrases of psalms but was loaded with errors. Despite its flaws, 1,700 copies were printed by Glover's business.

Glover passed away two years after she married Henry Dunster, and the business passed to her chief assistant's son, Matthew Daye. Once Matthew died, the business passed to Samuel Green, who printed 1,500 copies of the Bible in a Native American language. This is just one example of the influence that Glover had in what is now the United States. A century later, Ben Franklin, one of the Founding Fathers, used the business she had founded to cut the country's ties with England.

The printing press in the United States not only revolutionized the mass production of books, but it also made reading a common skill of the people rather than one reserved for the upper classes of society. People could read the Declaration of Independence that their country had used to declare its independence from England. Over time, the printed world became a lot bigger—compare the 1,500 copies of the Bible from the mid-1600s to the number of Bibles that now exist in the United States.

Today, most people are literate, and most homes have at least a few books in them. When pastors and priests read passages in church, people can follow along with their own copies of sacred texts. The ability to read and buy affordable books is a circumstance of modern life. This is only a reality in the United States today because of Glover's contribution to the intellectual growth of the 13 colonies.

Godfrey, Thomas (1704–1749)

Thomas Godfrey was an American inventor, mathematician, and artisan. He invented the octant, an important navigational instrument, at about the same time that an English mathematician, John Hadley, also created one.

Godfrey was born in 1704, in Bristol, Pennsylvania. He was apprenticed to a glazier as a youth and entered the trade as an adult. He was encouraged to study science and mathematics by James Logan, a botanist and future governor of Pennsylvania. He was also friends with Benjamin Franklin at a young age, but their friendship soured when Franklin rejected marriage to a relative of Godfrey's wife.

Godfrey dedicated himself to the creation of a navigational instrument called an octant. An early version of this instrument was invented by Sir Isaac Newton around 1700, but neither he nor the prominent astronomer Sir Edmond Halley, who saw a detailed description of it, ever published anything about this octant. Like the later devices invented by Godfrey and Hadley, this device consisted of a telescope that is mounted vertically; the horizon is viewed through an angled mirror while the telescope is fixed on a star. An index arm is adjusted until the horizon and star appear to be aligned; the user can then measure the exact angle by looking at the measurement inscribed on the index arm. This let them determine the correct time and thus longitude. The device was called an "octant" because it allowed users to measure angles up to 45 degrees: one-eighth of a circle.

Godfrey became interested in this project by studying astronomical devices and quickly realized the commercial potential of such an invention in an age of sail. He realized that while the octant was technically feasible, creating a portable version was extremely difficult. Godfrey constructed a prototype based on a cruder instrument called a quadrant in 1730, which a Philadelphia captain agreed to take to sea that year. The captain reported excellent results to Godfrey upon his return in mid-1731.

Godfrey demonstrated the octant to Logan, who agreed to present the device to the Royal Society in London. He was delayed a year, however, and in the meantime, the English mathematician John Hadley had come up with a similar device and presented it to the Royal Society. While no one has ever definitively

proven whether Hadley or Godfrey invented the octant first, Hadley announced his first experiments to the Society in 1731, at the same time that Godfrey was finishing his prototype. As vice president of the Royal Society, Hadley was prominent enough to receive a patent without contest in 1734.

Godfrey protested and noted that Hadley's nephew had been present at an early demonstration. The Royal Society did not relent but did eventually grant Godfrey a cash reward for his work. While Hadley called his device a "reflecting quadrant," today the common term is "octant," the name that Godfrey gave to it. In 1749, Godfrey died; in the same year, Hadley's patent expired, and the octant entered widespread use around the world.

Iron- and Silversmithing

Iron- and silversmithing were first introduced to North America in the late 17th century. An ironsmith or silversmith is a craftsman who creates items out of that specific element. Some examples of silversmithing include the creation of dishes, vases, and silverware. Silversmiths cut and shape items from silver by heating up the metal, which allows easy shaping with a hammer or bending tools. Silversmithing was especially popular in the late 17th century, because, unlike the element gold, it has less value but is very similar in strength and purpose. Iron- and silversmithing was also in high demand during other periods, such as that of World War II. Not only was smithing good for

This daguerreotype of a blacksmith in his workshop ca. 1855 highlights his most important tools and his most frequent product: the horseshoe. (Library of Congress)

making household items, but it also was used to create weapons.

Ironsmithing began with blacksmithing. The process consists of heating the metal until it melts and then later cooling it after the item is made. Although very useful in many ways, ironsmithing was not always seen as a good thing; some early villages banned the process, saying it was evil because of its ability to create weapons. Blacksmiths also experimented with different types of metals to see if any were as resistant and strong as iron, leading them to discover other ways of dealing with iron and other metals. The process of shaping metal with a hammer is called "forging." In the smithing process, iron is heated

and its color changes with the temperature—from red to orange to yellow and finally, white. To see the color changes, blacksmiths work in low light. The finishing processes for the items made in iron- and silversmithing consist of smoothing, sharpening, polishing, and brightening. Blacksmiths have always been seen as artists for their ability to transform metal into useful items.

Today, silver- and ironsmithing are still used. Smithing is an art that can produce household items such as coffeepots and silverware for daily use. A new interest in smithing arose in the later 20th and early 21st century, creating an association of blacksmiths of almost 4,000 members. Old West theme parks such as Knott's Berry Farm in Buena Park, CA, may have small smithing stores where tourists can have items created. The blacksmiths in these parks also make horseshoes for the animals in the theme park. Smithing has come a long way, from creating weapons of destruction to household items to horseshoes.

Kentucky Long Rifle

The American long rifle, sometimes referred to as the Kentucky or Pennsylvania long rifle, was one of the first rifles to be mass-produced and used regularly for both hunting and war.

The Kentucky long rifle owes its origins to gunsmiths and craftsmen of Austrian and German descent. Up until the 15th century, muzzle-loaded firearms

used a barrel with a smooth bore, which required the projectile to be slightly smaller than the bore. This caused a loss of muzzle velocity and seriously degraded accuracy.

Sometime during the 15th century, Gaspard Koller of Vienna created a firearm with straight, parallel grooves inside the length of the barrel. In 1520, Augustus Kotter of Nuremberg is believed to have turned the grooves into a spiral along the barrel axis, thereby imparting spin to the projectile. Despite these achievements, smoothbore muskets were used by infantries for another 300 years because they did not suffer as much from the complication of fouling caused by black powder, which was difficult to clean from the grooves.

As more Europeans settled in the New World, German hunters and gunsmiths settled throughout Appalachia, notably Jacob Dickert, Robert Baker, and Martin Meylin of Pennsylvania. These craftsmen manufactured copies of the German *Jaeger* rifle with some important modifications, such as a longer barrel. European rifles had shorter barrels (30 inches or less) and used higher-caliber ammunition, which required more powder and lead. This was undesirable for hunters on foot in the American woodlands. By lengthening the barrel to 42 to 46 inches, the gun makers were able to use lower-caliber ammunition and less powder while improving the firearm's performance. After the Revolutionary War, trappers and explorers crossed the Appalachian Mountains westward with their long rifles and were greeted by the Cumberland Plateau and Kentucky's diverse wildlife.

The long rifle is particularly known for its pleasing aesthetics. Its long and gracefully carved stock was often made of maple, and many rifles had carved and decorated stocks that echoed trends in fine American furniture. While early versions of the rifle were quite plain, by the late 1770s, every surface that could be decorated on the rifle often was, from the wooden stocks to the metal flintlocks.

The rifle made its military debut in the French and Indian War or Seven Years' War (1754–1763). The long rifle had played a pivotal role in turning the tide of the American Revolution in favor of the colonial rebels. In December 1814, General Andrew Jackson assembled 4,500 troops that included 968 members of the Kentucky militia to fight the British in the battle of

New Orleans. The “Kentucky rifle” became legend in a song commemorating this event.

However innovative the Kentucky rifle was, it remained problematic for soldiers until the invention of the minié ball, a rifle bullet that proved considerably easier to load and more stable in its flight than previous rifle balls. By the 20th century, the Kentucky long rifle had essentially disappeared from the American gun landscape except for in a few pockets of the Appalachian Mountains. In the late 20th and early 21st century, the rifle has enjoyed a revival, with boutique gunsmiths crafting modern interpretations of the centuries-old weapon.

Lightning Rod

Benjamin Franklin (1706–1790) invented the lightning rod in 1752. This invention resulted from Franklin’s study of electricity and his belief that his rod conductors could save humans and buildings from the destructive force of lightning strikes. A lightning rod is a metal rod attached to the top of a structure and connected to the ground through a wire. The electric charge from lightning strikes the rod, and the charge is conducted harmlessly into the ground.

Franklin had a lengthy résumé in an age when most people could only list farming or homemaking as their lifelong career path. During the course of his life, Franklin was an author, civic activist, community leader, diplomat, educator, humorist, inventor, philosopher, printer, politician and political theorist, postmaster, scientist, statesman, and, incidentally, one of the Founding Fathers of the United States. Four centuries later, he might also have included terms that were nonexistent during his lifetime in the 18th century, such as technological innovator. Along with that, another would probably have delighted him: storm

chaser. Once Franklin had an understanding of the behavior of electricity, which he is said to have found firsthand in a thunderstorm, he set about trying to protect buildings from the destructive forces of lightning.

Franklin became fascinated with the study of electricity, closely following the electrical experiments of other scientists. In 1746, he accidentally shocked himself during one experiment in his home laboratory. As soon as he recovered and while still experiencing numbness in his arms, he wrote about his experience and the effects of electricity on his body. Franklin continued his experiments, corresponding with other scientists. Often he had to invent new terms for elements of the little-known field of electricity, such as “battery,” “charge,” “conductor,” and “positive” and “negative” as descriptors of the charge—terms still in use today.

By 1749, Franklin became convinced that there were similarities between electricity and lightning. Both had a crooked direction, a crackling noise, and the same color of light. While some other scientists believed the same, Franklin was determined to find a way of proving it. He also began thinking about ways to protect people and buildings from the destructive effects of lightning—ergo, the lightning rod.

In June 1752, Franklin grew tired of waiting for other ways to test his theory, so, allegedly venturing out into a thunderstorm that hit Philadelphia, the legend of Franklin’s “kite-and-key” experiment was born. With his 21-year-old son William as the only witness, Franklin was said to have tied a metal key to a kite using only silk ribbon on his knuckles to protect his hand. Though some historians claim that Franklin did not go out into the worst part of the storm or that he withdrew at the first sign of danger, the story continues to resonate in popular history. Some writers assert that the kite-and-key episode was a myth propagated by Franklin himself 15 years later—one that had repercussions for the ultimate success of the American Revolution. Their theory is that the British feared that Franklin had created an electric superweapon.

Franklin’s initial thoughts about electricity focused on the ways in which the unseen force could be channeled to save humans and structures from lightning strikes. He theorized that pointed rods could draw the electrical fire from the clouds, thus preventing chaos and destruction. He developed the metal rods and began

marketing them to colonial Americans in the mid-18th century. Franklin was convincing enough that lightning rods could soon be found protecting colonial America's homes and buildings such as the Maryland State House. Its lightning rod was constructed and grounded according to Franklin's own direct specifications, and in almost 250 years of use, there has only been one recorded instance of lightning damage to the structure.

Primary Document: Frontispiece and Title Page of Benjamin Franklin's *Experiments and Observations on Electricity* (1774)

Benjamin Franklin's *Experiments and Observations on Electricity* was first published in 1751 as a 90-page pamphlet. The pamphlet comprised a collection of letters written by Franklin to Peter Collinson and other scientists at the Royal Society in London regarding his experiments with electricity. Because of public interest in Franklin's ideas and observations, the Society collected and published the letter. The first edition was

followed by various other editions and supplements until the 1769 publication of a hardcover volume of almost 500 pages that eventually went through several later editions and was translated into German, French, Italian, and Latin. Reproduced here is the frontispiece and title page of the 1774 edition.

Loom

In colonial America, England prohibited progress in weaving technology, prompting the birth of a home weaving moment. Looms became technological symbols of rebellion, disseminating mechanical thinking across social and economic classes, inspiring regional innovation, and creating physical emblems of self-sufficiency—home-woven textiles called “homespun.”

A loom enables a skilled operator to transform thread and yarn into fabric. Until the invention of mechanized power looms in 1790, all fabric for clothing, sheets, blankets, cloth bags, and even ship sails was woven by hand.

Beginning in the Middle Ages, woolen cloth production was a leading English industry. The powerful Weaver’s Guild controlled who could learn the trade and access loom technology. By the 17th century, a growing home-centered weaving movement threatened the Guild’s control, and it responded with suppressive regulation. Protestant weaving families felt persecuted and became early immigrants to the New England colonies. Some secretly brought their precious looms with them.

The looms that colonists brought to the New World were 11th-century technology. Four-post English box looms produced fabric narrower than three feet, but they offered options for intricate patterns. Cantilevered looms made bed-width fabrics but with less pattern capability.

A loom produces cloth by holding threads at right angles to each other as they are interwoven. “Warp” threads run the length of the fabric and provide its foundation. These long threads must be set up precisely on the loom for the cloth to be straight, square, and evenly patterned.

The threads running perpendicular to the warp are called “weft.” Weft thread is spooled out from a “shuttle” as it is alternately woven over and under the warp threads.

The English box loom had additional wooden bars that could change which warp threads were being woven, thereby creating patterns. After each pass of the shuttle through the warp, a wooden or metal bar tapped the weft threads tightly into place to make a smooth, solid fabric.

An English box loom’s wooden frame stood up to seven feet tall and covered an area similar to a four-poster bed. Though it could be taken down and transported, a loom was a large, complex machine. A family might devote an entire room or loft to a loom and textile production.

Initially, colonists were supplied with or purchased all of their clothing and textiles as England maintained its monopoly on woven woolen goods.

New England winters, however, were colder than expected, supply ships were fewer, and income for purchasing clothing was lower. Supplemental production of wool yarn became an important household endeavor. By 1656, Massachusetts Bay required all women and children to spin and process wool when not busy with other tasks. Processing flax plants into linen also became a practical necessity. Flax grew naturally in North America, and by 1640, Jamestown colonists were required to grow and process an annual minimum amount of flax or be fined.

While England and Holland discouraged or prohibited colonial textile production, a large number of early immigrants were skilled weavers. The combination of need and knowledge built a home-based movement for creating woven textiles for personal use. Most villages had a man, woman, or family that provided weaving services for fee or barter. Looms could not be imported, but weavers worked with wood craftsmen to replicate the few looms that had been smuggled into the colonies. Loom technology, which was closely controlled in Europe, was openly shared.

Colonists did not physically change loom technology, but they experimented with fibers and pattern. Scotch-Irish immigrants in New Hampshire were linen weavers. Wool shortages inspired combinations of linen warp with wool weft. The mixed-fiber cloth—called “linsey-woolsey”—was lightweight and strong like linen, yet warm and fire resistant like wool. Dutch-speaking German immigrants in Pennsylvania also had expertise in weaving linen. They developed a pattern technique called “American double-weave” or “double-face.”

Double-weave used the same looms but involved two layers of warp threads—one of colored wool and one of white wool or linen. This meant that two layers of fabric were woven simultaneously, one above the

other, and interwoven. This technique was typically used to produce blue-and-white geometric-patterned bed coverings. The blanket-like textiles had a white pattern with a blue background on one side and a blue pattern with a white background on the reverse. The light and dark sides inspired the name “summer-winter.”

Large Southern plantations employed experienced Irish linen producers to train African slaves in spinning and weaving. The rough linen they produced, referred to as “Virginia cloth,” was primarily used for slave clothing.

Through periods of war and economic recession, home-produced textiles provided a valuable alternative to expensive imports and became a patriotic symbol to unify colonists. The English regarded “homespun” both as a lower-class nuisance and a threat.

The English Wool Act (1699) tried to stop colonial manufacturing by prohibiting the sale of wool products between colonies or for export. The 1764 Sugar Act taxed imported fabrics and silk, convincing even wealthy colonists to embrace homespun clothing as a protest against English taxation. Large groups of women spinning in public or home weavers producing fabric were peaceful demonstrations against English rule.

During the Revolutionary War, Martha Washington used her plantation weavers to make wool cloth for soldiers’ clothing. She even recycled red silk yarn from George’s old socks to make a red-striped homespun fabric for herself. Throughout the colonies, the home weavers contributed to the war effort by creating wool coats for soldiers.

Following independence, the new country struggled financially, and government leaders discouraged

consumption of imported products. Producing homespun clothing again demonstrated patriotic nationalism. More looms and spinning wheels were produced, but they were old technology. American invention first impacted the production of traditional tools like wool cards.

The diary of Martha Ballard (1735–1812) provides rare documentation of home-based textile production and the economic benefit of a home loom. For a generation, industrialization did not eliminate the home weaving movement. Looms and spinning wheels continued to be passed down through families as long as the American frontier was being settled and homespun had value in a barter economy.

Primary Document: Excerpts from the Diary of Martha Ballard Describing Home Weaving (1787)

Colonial Americans experienced a shift in the gendered work of spinning and weaving. Previous to the decades surrounding the American Revolution, home weaving was seen as men’s work, and also as a full-time occupation. New home looms transformed the work of weaving into women’s work that could be

done alongside other domestic tasks. The following are excerpts from Martha Ballard’s diary, suggesting the kinds of work involved in home weaving and the way that work was integrated into domestic life. The entries also illustrate how weaving was a collaborative labor and not one undertaken by women alone.

Lucas, Eliza (1722–1793)

Eliza Lucas was born in the British West Indian island colony of Antigua. Best known as an innovator in the field of agronomy and as the mother of two influential men in American revolutionary history, Lucas entered the world in a time and place of great change in terms of both the spread of empire and the expansion of agricultural and economic pursuits in recently settled parts of the Americas and the Caribbean. As a botanist and follower of Enlightenment principles in both her scientific and personal endeavors, Lucas helped shape the economic and political history of America.

Lucas spent her youngest years immersed in the world of agriculture on the sugar plantation owned by her father Captain George Lucas. In 1732, Captain Lucas sent his daughter to England to be educated, selecting courses in mathematics, bookkeeping, geography, history, literature, and her greatest interest, botany. When she completed her formal education in 1738, she returned not to Antigua but to her father's South Carolina plantation, one of three he owned in that colony. Upon Captain Lucas's recall to Antigua for military service, the 16-year-old Lucas found

herself in charge of all three plantations as well as the care of her ailing mother and younger sister.

By educating her well and nurturing her natural talents and intellect, Captain Lucas had prepared his daughter to brilliantly manage plantation affairs. Her natural affinity for botany and the determination to make the plantation prosper encouraged her to experiment with various crops, the most important one being indigo. Early attempts at indigo culture had been unsuccessful, and rice was the most important export crop for South Carolina. By the time Lucas began her experiments, rice culture had become less profitable, leaving growers to search for an alternative staple crop, and indigo looked promising.

Many women of Lucas's social class studied botany, but few followed it with her purpose or intensity. She kept detailed records of her experiments in the improvement of indigo culture from planting to processing. When she married planter and attorney Charles Pinckney in 1744, she cemented her relationship with a man who knew and appreciated her aptitude and who became a cheerleader for her accomplishments. Pinckney spread information regarding his wife's experiments and promoted indigo production to a broad spectrum of South Carolina agriculturists.

Lucas's methods regarding the growth and processing of indigo helped to produce a better-quality product and expand production, while her influential husband secured a royal subsidy on South Carolina indigo. As a result, between 1744 and 1774, South Carolina's production of finished indigo grew from almost zero to over a million pounds. While this represents Lucas's main accomplishment, she also worked to improve other crops and conducted research in other agronomy-related methods that are commonplace today, such as intensive farming, crop rotation, and grafting.

Her two sons, Charles Cotesworth and Thomas, were prominent in the history of revolutionary America and the Early Republic; her daughter, Harriott, is best known for the preservation of her mother's letterbooks, a three-volume set that extends from 1739 to

1762 and provides extensive information regarding Lucas's life and interests.

Eliza Lucas Pinckney died in Philadelphia in 1793, a victim of breast cancer.

Primary Document: Letter of Eliza Lucas to Her Father (1741)

Eliza Lucas Pinckney's letterbook contains letters written between 1739 and 1762. The collection is considered one of the finest primary document sources of plantation and family life written by a woman of the time. The following is a letter Lucas wrote to her father in 1741 when she was 19 years old, discussing a variety of topics, including farming and planting. Note that for Lucas, domestic, family, and farming details are intertwined.

June 4, 1741

Never were letters more welcome than yours of Feb. 19th and 20th and March the 15th and 21st, which came almost together. It was near 6 months since we had the pleasure of a line from you. Our fears increased apace and we dreaded some fatal accident befallen, but hearing of your recovery from a dangerous fitt of Illness has more than equaled, great as it was, our former Anxiety. Nor shall we ever think ourselves sufficiently thankful to Almighty God for the continuance of so great a blessing. I sympathize most sincerely with the Inhabitation of Antigua in so great a Calamity as the scarcity of provisions and the want of the Necessarys of life to the poorer sort. We shall send all we can get of all sorts of provisions particularly what you write for. I wrote

this day to Starrat for a barrel [of] butter. We expect the boat dayly from Garden Hill [plantation] when I shall be able to give you an account of affairs there. The Cotton, Guiney corn, and most of the Ginger planted here was cutt off by a frost I wrote you in [a] former letter we had a fine Crop of Indigo Seed upon the frost took it before it was dry. I picked out the best of it and had it planted but there is not more than a hundred bushes of is come up—which proves the more unlucky as you have sent a man to make it. I make no doubt Indigo will prove a very valuable Commodity in time if we could have the seed from the west Indias [in] time enough to plant the latter end of March, that the seed might be dry enough to gather before our frost. I am sorry we lost this season. We can do nothing towards it now but make the works ready for next year. The Lucern is yet but dwindling, but Mr. Hunt tells me 'tis always so here the first year. The death of my Grand-mamma was, as you imagine, very shocking and grievous to my Mama, but I hope the considerations of the misery's that attend so advanced an age will help time to wear it off. I am very much obliged to you for the present you were so good to send me of the fifty pound bill of Exchange which I duely received. We hear Carthagene is taken. Mr. Wallis is

dead. Capt. Norberry was lately killed in a duel by Capt. Dobrusee, whose life was dispaired of by the wounds he received. He is much blamed for querrelling with such a brawling man as Norberry who was disregarded by every body. Norberry has left a wife and 3 or 4 children in very bad circumstances to

lament his rashness. Mama tenders you her affections and Polly joyns in duty with My Dr. Papa Y[our]. m[ost]. ob[edien]t. and ever D[evoted] D[aughter] E. Lucas

Masters, Sybilla (c. 1675–1720)

Sybilla Righton Masters was an American inventor from Pennsylvania. She was the first American colonist to receive an English patent, and she ultimately secured two: one for a corn grinding machine and another for a weaving technique initially designed for palmetto leaves.

Sybilla Masters was born to William Righton, a merchant and mariner, and Sarah Murrell. Her exact birth date and place of birth are unknown, but her Quaker father immigrated from Bermuda to the colony of West Jersey in 1687. Sometime between 1693 and 1696, Sybilla married Thomas Masters, a successful merchant and landowner. The couple would eventually have four children. Thomas was a prominent member of Philadelphia's Quaker community, serving in a number of political positions, including alderman of Philadelphia, mayor in 1707 and 1708, and provincial councilor, 1720–1723.

In 1712, Masters traveled to London to secure patents for her inventions, since Pennsylvania was not yet granting its own. Masters had to apply using her husband's name, since women were unable to receive patents under English law. She did, however, receive credit in the application's description as the inventor. King George III eventually granted her request on November 25, 1715. Her corn milling device used a stamping process to crush corn, an improvement over the previous methods, which used heavy millstones to grind the grain. Masters's device was inspired by her observations of Native American women's work with maize. Her machine was powered by horse or water and consisted of a series of heavy pestles that descended through a long wooden cylinder into a

continuous row of mortars, which held the corn kernels. The crushed product then descended into a row of basins for drying. The Masterses called the resulting meal "Tuscarora Rice"—today known as "hominy" or "grits." The couple was hoping to export their product to England, but it was never popular there.

During Sybilla's absence, Thomas Masters acquired the Governor's Mill, a mill built for William Penn in 1701. He used it to produce large quantities of the meal, which he promoted as a cure for consumption. Sales were disappointing, however, and Masters soon converted the mill to other purposes.

Sybilla Masters acquired the second patent in London, on February 18, 1716, for a method of weaving and staining palmetto and straw leaves. While in London, waiting for news on her patent applications, Masters opened her own shop, the West India Hat and Bonnet. Having been granted a monopoly on the importation of the palmetto leaf from the West Indies, she used her new process to weave a variety of goods, including adornments for bonnets, baskets, mats, furniture coverings, and childbed baskets. Masters returned to Philadelphia in 1716. Her husband petitioned the provincial council to record and publish her patents in Pennsylvania, which it did on July 15, 1717. Masters died in 1720, probably in Philadelphia.

Mather, Cotton (1663–1728)

Though Cotton Mather is primarily known for his role in the infamous Salem witchcraft trials, he was also a well-known and highly regarded scientist. His international fame is witnessed by the conferring of an honorary doctorate on him in 1710 by the University of Glasgow.

Mather was born in Boston, Massachusetts Bay Colony. He had illustrious ancestors on both sides of his family. His mother was named Maria Cotton, and his father was the famous Increase Mather. His maternal grandfather was John Cotton, and Richard Mather was his paternal grandfather. Each of these men was a famous Puritan minister.

Mather was well educated. Before attending Harvard College, he studied at Boston Latin School and was entered into its Hall of Fame. Mather was a Harvard College graduate, earning an AB in 1678 and an AM in 1681. Like his father, he became a Puritan leader in New England as a minister and an author of books and pamphlets. After completing his undergraduate and graduate studies, he became an assistant pastor at Boston's original North Church, under his father's leadership. Mather succeeded his father as pastor in 1685. Despite his heavy responsibilities there, he managed to author over 450 books and pamphlets. Mather hoped to become president of Harvard College, but for various reasons, including his support of the Salem witch trials, he was denied the position.

Mather had a lifelong interest in science. He was a strong supporter of inoculation as a means for preventing disease. He had learned of the practice in 1706 from one of his father's slaves and, after educating himself on the possibilities of inoculation, pressed for its more widespread use in the colonies. Significant cultural forces, including Benjamin Franklin's brother James, opposed inoculation. The ensuing controversy not only embroiled the New England medical community but the Puritan hierarchy as well. Many Puritan leaders argued that smallpox was part of God's plan and that suffering should not be prevented. Mather continued to argue for the efficacy of inoculation until his death.

He also experimented with plant hybridization. His theory is presented in his work *Curiosa Americana* (1712, 1714), and it was the basis of Carl Linnaeus's

While Cotton Mather is primarily famous for the part he played in the Salem Witch trials, he was also a great supporter of smallpox vaccinations. He learned of vaccinations from his slave Onesimus, who had been inoculated in Africa. (Library of Congress)

system of botanical classification. In 1713, the Royal Society of London honored Mather, naming him a fellow and making him only the eighth American to receive that title.

Mather was instrumental in establishing the mood and manners for third-generation Puritans. He sought to reconcile Calvinistic beliefs with modern science. In his works, he moved toward what he thought of as rational religion. Perhaps the most influential of his writing was the *Magnalia Christi Americana* (1702) in seven volumes. These books contain biographical and historical information supporting his teachings on rational Christianity.

At the same time, Mather was also a major influence on American science. His work on the hybridization of corn was significant in the later development of Linnaeus's botanical typology. His own work was influenced by that of Robert Boyle, especially *The Usefulness of Experimental Natural Philosophy*.

Interestingly this work influenced not only Mather's scientific ideas but also his religious teachings and observations.

Despite his outstanding efforts in science and rational religion, Mather is remembered mainly for his role in the Salem witch trials. Mather's 1689 work *Memorable Providences* is often cited as the cause of the 1792 trials. It is an account of the assumed afflictions of children in a Boston family. The alleged culprit was an Irish servant, a Catholic named Goody Glover. She was accused and convicted of being a witch and executed. He vigorously defended the legitimacy of the trials and never issued any denials or statements of doubts concerning them.

Robert Calef, a contemporary of Mather, stated that this work was the cause of the Salem witch trials, noting that Mather was very involved in them—more so than any other minister in America. He “Intrigue[d] with that Child,” a child he took into his home, to work against the accused women. His printed accounts, said Calef, stirred up the fires and threatened the stability of the area as well as provoking the execution of dozens of men and women.

Not only did Mather not recant his support of the trials, he continued to defend them long after most supporters had recanted and apologized for their actions. Indeed, he wrote *Wonders of the Invisible World* (1693) in his defense of the trials. It supported Lt. Governor Stoughton's role in the trials and offered his views on the trials themselves. In fact, he became stronger in his defense of the trials as years went on and compared the ones in America with those in Europe. He also included several of his sermons defending his views on the types of evidence that could be used, including spectral evidence—the information that witnesses garnered from ghosts. In the end, Mather's complicity in the witch trials obscured both his religious and scientific achievements. He died in 1728.

Natural History

Natural history is the observation, description, and collection of quantitative data concerning natural systems, living species, and nonliving elements, with an emphasis on relationships. In the United States, the natural history movement of the mid-18th to the 19th century disseminated scientific information and ideas to an economically and socially diverse population; popular science was no longer an exclusive privilege of the upper class. This was not an organized movement but rather the timely intersection of visionary individuals like Benjamin Franklin (1706–1790), the Quaker religion, the free flow of ideas in a newly independent republic, and the ascension of natural history devotees like Thomas Jefferson (1743–1826) to governmental power.

In the 18th century, the term “scientist” did not yet exist. Scientific pursuit was not considered an occupation. In 1723, second-year students at Harvard College (now Harvard University) studied a few weeks of “natural philosophy”—philosophical explanations for natural phenomena—not data-based science. While modern science divides natural history into specific fields (biology, botany, geology, paleontology, climatology, astronomy, physics, etc.), natural history in the 18th century was all-inclusive. Inquiring individuals made observations and asked: What is this? Why does it behave this

way? How is it different or similar? And, how are all of these pieces of the natural world interconnected?

Natural history study began in Europe, where a few individuals, mostly wealthy gentlemen, had the opportunity to pursue science as an avocation. The Royal Academy (1660) in England and the French Academy of Sciences (1666) were membership organizations founded to support scientific inquiry and peer review of experiments and hypotheses.

Early English colonists spent most of their time working to obtain food, clothing, and shelter; pure scientific pursuit was limited to upper-class or wealthy individuals, such as botanist Jane Colden (1724–1766). For inquiring individuals, scientific investigation occurred within the course of daily work. Ironworker Joseph Jencks (1599–c. 1682) experimented with physics as he generated hydropower for his iron foundry. Eliza Lucas Pinckney (1722–1793) conducted horticultural studies in the operation of her plantation.

Benjamin Franklin incorporated his broad scientific interests into his printing business by publishing science-related articles in his *Pennsylvania Gazette* newspaper. A young Franklin had access, through wealthy friends, to rare and expensive scientific books. By publishing ideas from these sources in his various publications, Franklin disseminated privileged information to the general public. He initiated Americans into the sciences and became a catalyst advancing the natural history movement.

Franklin encouraged readers to document observations of natural phenomena and to collect data on weather. He inspired scientific inquiry while cultivating a future audience for his almanacs. In 1743, Franklin and other like-minded individuals established the American Philosophical Society (APS) in Philadelphia to investigate natural history and promote innovation. Franklin's first experiments with electricity were conducted on loaned APS equipment. As the largest city in the British colonies, Philadelphia was influential, and its Quaker roots created a fertile birthplace for the rise of science in North America.

The Quaker religion emphasizes individual actions over biblical scripture. Seeking truth through inquiry shapes the Quaker worldview and is conceptually similar to the scientific method. Quaker society offered the greatest gender parity of the time and nurtured

inventors of both genders, such as Hannah Wilkinson Slater (1775–1812) and Daniel Wilkinson (1771–1852). Franklin and the Quakers believed that understanding natural phenomena could provide solutions to everyday problems.

As a founder of the College of Philadelphia (now the University of Pennsylvania), Franklin approved the first natural history courses on plants and animals in the colonies (1756). In 1786, the Quaker-founded College of Rhode Island (now Brown University) became the first to designate a natural history professor: Benjamin Waterhouse (1754–1846). Waterhouse later cofounded Harvard Medical School and become the first physician to test the smallpox vaccine in the United States.

From Boston to Philadelphia, lectures and demonstrations on topics varying from blood circulation to electricity intrigued the public. The APS sponsored astronomer David Rittenhouse's (1732–1796) public observations of the 1769 transit of Venus outside the Pennsylvania State House.

While the Revolutionary War sidelined science, it also brought the country's influential men together. The first four American presidents were members of the APS. Understanding nature and natural resources was vital to productive agriculture, and it improved manufacturing and the success of the new nation.

Thomas Jefferson became president of the APS and vice president of the United States on the same day. Natural history was his passion, and Jefferson was an avid data collector. He documented experiments with agricultural crops, including 19 varieties of peas, and compiled the first known list of North American birds using Carl Linnaeus's taxonomic naming classifications.

In 1803, Jefferson's background prompted the first governmental funding for scientific exploration. He sent the Lewis and Clark Expedition to explore the newly purchased Louisiana Territory and to collect animal and plant specimens, document soils and geology, and observe Native American agricultural practices. The APS displayed some of the Expedition's specimens.

Charles Willson Peale (1741–1827), APS member and painter, brought science to everyday people through the nation's first natural history museum.

He also introduced Jefferson to the Prussian natural history polymath, Alexander von Humboldt (1769–1859). In 1804, Humboldt was returning to Europe following a five-year expedition through South and Central America. He shared with Jefferson his observations, data collection methodologies, and bold visions on natural history.

Humboldt joined the APS, corresponding with Jefferson and other members throughout his life. His numerous books popularized natural history. Like Franklin, he presented complex science to common people. His narrative prose interlaced data with poetic descriptions. Humboldt wrote of the earth as a “living whole” where all things were interconnected—living species, the land, air, water, and climate. His interwoven web of life defines modern ecology and ecosystems.

Introducing Humboldt to the American public ushered in the era of Humboldtian science. Americans became obsessed with specimen collecting—of bird eggs, butterflies, and more. Even a teenage Emily Dickinson (1830–1886) labored over her “herbarium”—a book of pressed plants for natural history study. Humboldt’s writings inspired generations of American scientists, inventors, and writers: Samuel Morse, John James Audubon, Louis Agassiz, David Henry Thoreau, Franz Boas, and George Perkins Marsh.

Onesimus (fl. 1706–1716)

The practice of inoculation came to the United States through the knowledge of Onesimus, an enslaved man owned by Cotton Mather, a prominent New England theologian and minister of Boston’s Old North Church. Little is known of when and where Onesimus was born. He appears first in American history in a note in Mather’s diary for December 13, 1706, where the minister mentions the purchase. Mather also documented the fact that he named Onesimus after a biblical slave who escaped from his master, an early Christian named Philemon.

Mather’s later diary entries detail the fact that Onesimus eventually married and had a son, Onesimus, who died in 1714. Two years later, Onesimus earned his freedom from Mather in or around August 1716 by negotiating to continue to provide services to the Mather family when needed as payment for that freedom. The two men wrote a detailed contract in which they agreed that such services would include shoveling snow, piling firewood, fetching water, and carrying corn to the mill. Onesimus also helped fund the purchase of another enslaved man, Obadiah, who could take his full-time place in the Mather home.

Onesimus remained connected to the Mather family, which benefited them in many ways, the most important being during the smallpox epidemic that swept through Boston in 1721. Mather wrote a letter to the Royal Society of London, proposing a possible way to stop the spread of the devastating disease. He called his method “inoculation” and explained that he had learned the process from Onesimus some five years earlier. At that time, Onesimus explained the practice popular in Africa and demonstrated by cutting Mather and inserting some of what he called “smallpox juice” from someone suffering the disease. Mather discovered that other Africans in Boston practiced inoculation and learned that those with a inoculation scars indicating immunity cost more in slave auctions.

Mather then advocated for public inoculations, but most doctors rejected the idea of infecting a person with smallpox. It seemed counterintuitive to their training, yet in a survey of the nearly 6,000 people who caught smallpox between 1721 and 1723, only 2 percent of the 600 Bostonians inoculated against smallpox died, while

14 percent of those who were not inoculated died. With these results, inoculation served as the most trusted way of treating the disease until English physician Edward Jenner created a vaccine in 1796.

A side story to that of Onesimus comes from the fact that the 15-year-old Benjamin Franklin witnessed this outbreak and the results of inoculation and, as an adult, became an advocate of inoculation when his own son died of smallpox.

Peale, Charles Willson (1741–1827)

Charles Willson Peale was a painter and natural history scholar during the Early Republic era of the United States. His work in natural history led to the creation of the first systematic museum of natural history and art in North America. Peale's philosophy and methodology for exhibiting natural history to the public laid the foundations for many elements of museum operations common today, while introducing the public to specimens from several scientific expeditions.

Born in 1741, Peale's family was left destitute by the death of his father when he was just eight years old. Peale and his mother moved to Chesapeake, where he attended charity school. After school, Peale was apprenticed to a saddler but quickly got into debt. To pay off his debts, Peale began painting miniature portraits, revealing an innate talent for art. During the late

1760s, Peale traveled to London to study with the artist Benjamin West. Upon returning to the United States, Peale became well known for his life-size portraits of planter society that emphasized family harmony and affectionate domestic relationships. He continued painting while serving as a militia officer during the Revolutionary War, painting over 1,200 portraits of early leaders, military heroes, important allies, and landscapes. After the war, he opened a small art museum in a wing of his home in Philadelphia.

Following the discovery of mastodon bones at Big Bone Lick in Kentucky during the 1780s, Peale acquired and displayed the bones at his art museum. His interest in natural history grew, and together with his sons, Peale united his paintings with a passion for collecting natural history specimens. By July 18, 1786, Peale had amassed a large collection of specimens and exhibited them at his own museum in Philadelphia—founding the earliest systematic museum of natural history and art in North America. Peale's museum displayed specimens according to classification principles established by Swedish scientist Carl Linnaeus in *Systema Naturae* (1735), which divided specimens into three kingdoms: animal, vegetable, and mineral. Specimens were then classified by divisions into classes, orders, families, genera, and species. Peale's collection of minerals, shells, fish, birds, insects, mammals, and ethnographic artifacts were arranged in hierarchical order, with his portraits of influential Americans as the highest level of life.

In 1801, Peale recovered two nearly complete mastodon skeletons from what is now Peale's Barber Farm Mastodon Exhumation Site near Montgomery, New York. Peale took these skeletons to his museum, where he reassembled one, sculpting the missing pieces to present the remains of an entire animal to the public. It was the second time that a fossil skeleton had been assembled anywhere, and its presence fueled debates on extinction and evolution. This display was such a success that the second skeleton was taken on tour to New York City, Pealeton, and London. Peale commemorated the discovery of the skeletons in his painting *Exhumation of the Mastodon* (1806–1808), which showed a crew of men removing bones from a marl pit.

Peale centered his museum on the philosophy of public utility, believing that museums should be based

on their capacity to educate and amuse the public. The museum was made accessible to a variety of audiences, including those of different social ranks, genders, races, political affiliations, and religions. His collection was amassed through personal effort and the solicitation of donations from the international community. He pursued an aggressive marketing campaign that focused on the economic, social, scientific, moral and religious implications of his exhibitions. Peale also instituted the sale of museum souvenirs and utilized subscription memberships to provide a steady patronage base. His philosophy was adapted by contemporary American museums and continues to be followed by many museums today.

By 1802, Peale's collections had grown to the point of needing a larger space. He received permission to use the second floor of the Pennsylvania State House (now known as Independence Hall) to merge the natural history and art collections with the symbolic center of government. The museum would move several more times during the early 1800s, due to the increasing size of its collections.

In 1818, Peale appealed to the U.S. Congress to recognize his museum as a national institution. Although the government did donate minerals and Indian artifacts from the Lewis and Clark Expedition, Congress refused to grant official recognition or funding. Because of this, Peale opted to establish the museum as a corporation with a board of directors—another model that contemporary museums adopted.

When Peale died in 1827, the museum housed over 250 quadrupeds, 1,310 birds, over 4,000 insects, 8,000 minerals, 1,044 shells, several hundred fish, and

over 200 snakes, lizards, turtles, and tortoises. It was also home to ethnographic artifacts from major scientific explorations, including the Lewis and Clark, Pike, and Long expeditions. The museum had become the primary resource for American natural history and drew public visitors from all over the world. It was depicted in one of Peale's last paintings, *Artist in His Museum* (1822), which showcased the variety of natural history specimens—including the skeleton of the mastodon he had recovered in 1801—as well as guests viewing the collections with awe.

After Peale's death, the museum was managed by Peale's son, Rubens Peale, until it declared bankruptcy in 1842. The museum's collections were dispersed, some never to be seen again—but Peale's philosophies on the purpose and functions of a museum lived on as the basis for modern American museums.

Primary Document: Letter of Charles Willson Peale to Thomas Jefferson Regarding New Agricultural Inventions and Innovations (1815)

Soldier, scientist, and inventor Charles W. Peale carried on a correspondence with Thomas Jefferson about their mutual interests in farming and inventions. Peale's May 1815 letter, excerpted here, describes windmill sails and a corn shelling machine, as well as a discussion of the inventions and innovations that Jefferson had discussed in his previous letter. The letter suggests the wide field of interests that

men like Peale and Jefferson had, unlike the present tendency to specialize in a single field.

Belfield May 2^d 1815.

Dear Sir

Your favor of March 21st came in due time—and a rainy day now gives me leasure to write, to thank you

for your interesting letter, abounding with useful information to the farmer and Mechannic. You observe that the winter has been hard.—the Spring appears to be backward, I hope it will be favorable to our fruits, the last year gave us but little. My small green House accidentally constructed keep the Plants during the severity of the winter remarkably well. To trace a spring in my falling Garden, we had dug out a large hole in the Earth, this hole I thought if covered over might be useful to keep Turnips and other roots, therefore it was arched over, the tryal proved that it was too warm and moist, every thing of the vegetable for our tables, grew & were spoiled. I built a front, to the south, of Glass windows, in which front building are put the pots of Plants on shelves, no fire is necessary to keep Plants in such situation. The spring is covered in the cave, and the water by a trunk carried to a bason below. I believe that the springs within the Earth are all seasons of equal temperature, that our feelings induce a belief that they are warm in winter & cool in summer; the same with sellers and Caves—Perhaps a Green-house of considerable size might in this manner be constructed to save all the expence of fuel; a great quantity of air kept from impression of the external air by a thick body of Earth, would mix with the air in the front of such cave, where the necessary light must be had for Plants, But to render such Green-house complete it might be necessary to have double windows, this of course would be expensive, yet in the end a great saving, for as Doct^r Franklin said, “it is cheaper to build two Chimnies than to keep one fire”—I do not think M^r Halls invention will benifit the farmer, it is necessary to plow the land to put it [in] order for other crops, and it is also necessary to manure the whole land to fit it to nourish the long extending roots of Corn. Our land properly prepaired will produce fine Corn in rows 5 feet apart and two or 3 Grains at 2½ feet distance, which were we to place the rows 6 feet apart I suppose is planting more corn on the acre, I have made no calculation on what the difference would be. Amongst a variety of cast mould boards, I could find none of the shape of that, your plan gives, and I had, some time past, meditated making some tryal at forming a patern to get some castings made, I could not determine on the material to make the patern—I was fearful of the warping of a thin patern of wood or pasteboard, but suppose there is no difficulty of casting from another casting, If I have your permission when I receive your Plow, will get

some cast by it, that others may be benefited by getting so perfect a form to so important an Utensil as the Plow. I have conversed with many engenious farmers who have thought that they knew how to make good forms to their mould boards, some have told me that after making their mould-boards to what they thought a good form and after plowing with them, that they observed at what points was most worn, that in such places they trimed off. my oppinion is that all the Mould boards I have seen, have hollows where they ought not to be, and such hollows brake the sods in the action of turning them over, thus increase^s the labour of breaking a tough sward in addition to that of turning it over.

With respect to the springs for sails of large wind-mills, I believe there will be no difficulty, or no more than in my small ones, they must be stronger in the proportion to their office—But in a large wind-mill I would not make each sail large, no wider than the common sheet Iron, preferring such to canvis, and being painted would be very durable. The spring should be regulated by a Screw. . . .

The end of spring with a link to connect to the staple in the sail, and this staple should be placed near to the joint of the sails motion, in order to obtain only a small motion of the spring. I have found that in my first plan of making the spring work or pins, that the constant motion on the pins subjected them [to] be soon worn out, the joints of the link should be strong or with washers to prevent as little wear as possible. long and continued motion will undoubtedly wear out by friction, therefore, in such parts as can be supplied with oil from resevoirs, should be adopted to save trouble and attention, such as the Boxes of the main shaft crank, and friction wheels.

The Corn shelling machine with 2 cylinders is a good invention; and I believe will work well with a small crank receive^s its motion from the foot of the person feeding it—mine is mooved by aband from a Drum in the mill—by the weight of a log of white oak 2 feet long & 20 Inches diameter, its motion from the foot with very little exertion will be powerful enough for the shelling, the young man who made that I have, told me of their working satisfactorlily where he made them (at Columbia)—I remember seeing a machine with a single Cylinder such as you describe at the Philosophical Society, exhibited if I remember right by the inventor, but I do not remember whether it was a solid or hollow

cylinder? the objection of not adapting itself to the different sizes of Corn at the time, Struck me, and thinking to obviate this fault I thought of placing strong springs over the axis—and intending to make such a machine, I spoke of it to the young man who by chance had been employed in making those of 2 Cylinders and by his recommendation I was induced to employ him to make me one. If you wish to have one I will order one to be made. I admire the simplicity of your machine for cutting straw—that I have made must have cost me near 20\$, and it is like many other of my contrivances, costing much more than can be saved of labour in my time. the chief consolation I have that I am amused, and by that and much labour I am kept healthy and happy—My Son Franklin has commenced making Machinery for carrying on the Cotton Business, and employs his two brothers in the work. Linneus and Titian, they all possess talents for mechanic labours—Franklin in one years practice, with Mess^{rs} Hodgson, English men bred to the machine manufactory, became one of their best hands.—The Youth was always emulous to execute his work in the neatest and best manner. Every machine they make use off, must be made by themselves, I cannot afford to purchase any thing more than the materials for them to work on. . . .

At Present I have very little trouble in the Management of the farm, having two young men that take all that care & labour off my hands—my principle work is in the Garden, and to put my thorn Hedges in good order, and also to do what I find is necessary to Machinery at the Mill—I had forgot one other of my employments, namely, to oblige some few friends by my giving them the means of masticating their food. I have for many years practiced the making of artificial Teeth of a variety of Ivory & by my practice have acquired the knowledge of giving relief in some difficult cases—but as all sorts of Ivory, bones, and even shells are all subject to decay—I have lately been preparing to make some essays at making them in Enamel—for the small quantity of work that I shall ever do, perhaps it is scarcely worth the trouble & expence of making a furnace & preparing the Materials & then make many tryals before I can expect to succeed to my satisfaction. Yet if I am successfull in making a good Enamel I may give an important business to some ingenious Person who may relieve the distresses of many who want teeth for health as well as beauty. I am not unconcious that I have mispent

much of my time, a steady habit to any one object perhaps would have been more advantagous, I can reconcile this conduct to myself, because it has constituted much of my happiness—but the judicious and prudent, will condemn me! It seems almost impossible to forbear putting my hands to execute what the fancy dictates, but having frequently trifled away my time I have of late paused, and turned over in my mind the means and the end, and sought advice from my friends. Yet at this moment I am doubtful whether my actions are governed by Wisdom—I frequently think that my Pensil ought not to lay Idle. I still fancy that I could produce things worthy of notice; more valuable than my mechanic labours, By a diversity of objects, times flies swiftly away like a dream.

I turn again to your interesting letter, and think how justly you describe the principle of the Pendulum's motion, it induces a desire to see what the man has done with his Pendulum moovements. The "Ingenuous friend at Albany," I think has not made any new discovery, Cranked axle-trees have long been used to lower the Bodies of carriages, and indeed the weight being placed low, appears to be the chief principle to prevent oversetting. Turning to the copies of my letters, I find that I had described the Corn shelling Machine in my letter of Dec:r 1813. By the use of it since that period I have found it very useful, and not much liable to derangement, the space between the large Roller & the frame where the Corn passes between the two rollers, must be small to prevent the cobs from getting in & breaking them but truth in moovement & strength of parts in proportion to the power required, must always insure the just operation of a Machine. I do not know that a log turned from the centre of its groath, would in any sensible degree become untrue by shrinking—I know that the rolling-press for copper plate printing sometimes require turning anew—whether it is caused by the axis not being put in the Center of the commencement of the groath of tree, or that one side may be of a more porous substance than another and thus be a cause of becoming untrue, should that be the case I see no other resourse in the corn shelling Machine but to fix a rest, and then drive the pins most projecting from the centre of Motion.

Since writing the above I have conversed with the Person who made my shelling Machine, and he says that Apple-Tree turned, in drying becomes oval, and Hickory next, but that white-oak scarcely alters in its

form from true roundness by seasoning. He says that he has a good log, and he will make a Machine for me when I may give him notice. I have desired him to save the stuff until I can hear from you. . . .

By keeping my letter open, and now & then taking up the pen, I have touched on a variety of subjects, and now think it time to conclude, well knowing that very little is worth your time of reading it, yet I am much interested in getting an answer to some parts, especially about the final disposition of the Museum. In the last year, twice, I have been in danger by accidents, of sudden death, I promise myself in future to be cautious, in my labours, to avoid danger—But dangers may happen even with the most prudent; then how

necessary it is to be always prepared against what cannot be foreseen—The government of our Passions, and prudential care will make man last untill the machine is worn out by age; natural decay, as all nature testifies. May you my dear Sir, last untill you feel no pain in leaving this world, is the earnest prayer of

your obliged friend

Priestley, Joseph (1733–1804)

Joseph Priestley was a philosopher, teacher, theologian, nonconformist, and chemist. He published numerous works on the topics of religion and science; however, he is best known for discovering oxygen. A Unitarian minister and friend to Benjamin Franklin, Priestley was forced to flee England because of his radical political and religious beliefs. In 1794, Priestley relocated to Pennsylvania, where he continued his research and became an influential figure in the development of chemistry in America.

Born in a small town near Leeds, Priestley was the oldest of six children. Reared in the Calvinist faith by his aunt and groomed for the ministry, Priestley at a young age displayed advanced intellect. His inquisitive nature led him to conduct experiments with gases. In 1767, he infused water with carbon dioxide and created carbonated water. Also in that same year, he published a work on the history of electricity. In 1774, he made one of the biggest contributions to chemistry with the discovery of oxygen.

Priestley conducted a series of experiments with a mouse, a burning candle, and a mint plant. He observed how long each lasted in a sealed jar, with the plant lasting the longest. Priestley conducted additional experiments with the objects together and observed that alongside the plant, both the life of the mouse and presence of the flame were extended. Priestley continued

his research with mercury oxide and noted that the gas released was distinctly different and better than common air. These numerous experiments culminated in Priestley’s discovery of oxygen; however, he incorrectly called the newly discovered gas “dephlogisticated air.” Even though others, such as Carl Wilhelm Scheele of Sweden and Antoine Lavoisier of France, experimented with oxygen, Priestley is credited with the discovery because he published his findings first.

Moreover, Priestley’s series of experiments were groundbreaking in that it paved the way for the study of ecology. In this area of study, Priestley was ahead of his time. It would be decades later before scientists gained an understanding of the connection between living things and their environments.

In addition to chemistry, Priestley shared his views on politics and religion. He supported the American and French Revolutions and embraced a liberal interpretation of Christian dogma. Priestley’s philosophical approach to theology led him to support the Unitarian faith. His left-of-center political and religious views caused tension with politicians, scientists, clergymen, and his congregation. Because Priestley had become a controversial figure in England, he and his family were forced to move to Pennsylvania in 1794, where he remained until his death in 1804. While in America, he continued his chemistry research and helped develop the study of chemistry there.

Rittenhouse, David (1732–1796)

David Rittenhouse was an important 18th-century American astronomer, inventor, and engineer. The multit talented Rittenhouse was a central figure in the development of items ranging from surveying tools to

Inventor, astronomer, and scientific instrument builder David Rittenhouse was the first director of the U.S. Mint. His Orrery, or mechanical model of the solar system, was admired by Benjamin Franklin and Thomas Jefferson. (Library of Congress)

the construction of one of the nation's first observatories.

David Rittenhouse was born on April 8, 1732, in Paper Mill Run, Pennsylvania, a small town near Germantown, itself a small town outside of Philadelphia. The son of Matthias Rittenhouse, a farmer, and his wife, the former Elizabeth Williams, Rittenhouse showed an early aptitude for math as well as exceptional mechanical skills. He also liked to tinker with farm technology and build new things. Applying those talents to books and using tools received from his uncle, Rittenhouse engaged in a process of extensive self-education. He first made mathematical instruments. He also constructed what is believed to be the first telescope built in the United States. At the same time, he established himself as a skilled maker of surveying tools. He served as the city surveyor of Philadelphia and also helped establish the boundaries of Pennsylvania, Maryland, New Jersey, New York, and the Northwest Territory.

His work in astronomy earned Rittenhouse his greatest fame within the scientific community. Among his many astronomical accomplishments was an early observation of the atmosphere of Venus. On June 3, 1769, he observed Venus's transit across the sun. He became so excited during the observation that he fainted. He also calculated the distance between the earth and the sun, coming quite close to the actual distance.

Utilizing his singular mechanical skills and mathematical knowledge, he designed numerous innovative astronomical instruments, including a pair of orreries (mechanical models of the solar system that predict the motion and positions of the planets) for what are now Princeton University and the University of Pennsylvania. His orreries could show both the lunar and solar eclipses as well as other phenomena for a period of 5,000 years. He also built an observatory on his father's farm just outside Philadelphia.

Beyond astronomy, Rittenhouse made the first man-made diffraction grating, conducted wide-ranging experiments that looked at the compressibility of water, and also considered the impact of heat on metal, wood, and magnetism. He made improvements on the famous Franklin stove and designed glasses for George Washington.

All of these efforts earned him great acclaim and recognition. In 1768, he was elected to the American

Philosophical Society, where he served as president from 1791 until his death in 1796. The recipient of numerous honorary degrees, he was recognized with membership in the American Academy of Arts and Sciences and was also named a fellow of the Royal Society in London. Rittenhouse was actively involved with higher education in Philadelphia, serving in a variety of teaching and administrative roles at both Philadelphia College and the University of Pennsylvania.

Rittenhouse played an active role in the American Revolution. Serving on the Committee of Safety, he supervised the casting of cannons, the development of rifles, and the location of both gunpowder mills and ammunition stores, as well as production of that equipment. Also, his surveying work helped the army plan defense efforts around Philadelphia. He also served in the Pennsylvania Assembly, on the War Board, and the 1776 Pennsylvania Constitutional Convention. He served the state of Pennsylvania as treasurer from 1779 until 1787, and in 1792, George Washington appointed him the inaugural director of the

United States Mint. As the mint director, Rittenhouse oversaw the minting of the first coins in the United States. He believed that coins should be beautiful and personally struck the first few, which were made from silverware donated to the mint by George Washington.

Rittenhouse married Eleanor Coulston, who died in childbirth in 1770. He married Hannah Jacobs in 1772. That union produced one child, which died in infancy. David Rittenhouse retired from the mint in 1795 and died on June 26, 1796, in Philadelphia.

Primary Document: Letter of Thomas Jefferson to David Rittenhouse (1778)

Primarily known for his work on the transit of Venus, David Rittenhouse also worked as a surveyor and state representative for Pennsylvania. In the letter here to Rittenhouse, Thomas Jefferson describes his own efforts to view an eclipse and offers advice to Rittenhouse on his astronomical clock. What is clear from the letter is that Jefferson regarded himself as a man of science and that he viewed Rittenhouse as an expert to whom he might turn for advice.

To David Rittenhouse Monticello in Albemarle, Virginia, July 19, 1778

DEAR SIR,

—I sincerely congratulate you on the recovery of Philadelphia, and wish it may be found uninjured by the enemy—how far the interests of literature may have suffered by the injury or removal of the Orrery (as it is miscalled) the publick libraries, your papers & implements, are doubts which still excite anxiety. We were much disappointed in Virginia generally on the day of the great eclipse, which proved to be cloudy.

In Williamsburgh, where it was total, I understand only the beginning was seen. At this place which is in Lat. 38 degrees-8' and Longitude West from Williamsburgh about 1 degrees-45' as is conjectured, eleven digits only were supposed to be covered, as it was not seen at all till the moon had advanced nearly one third over the sun's disc. Afterwards it was seen at intervals through the whole. The egress particularly was visible. It proved however of little use to me for want of a time piece that could be depended on; which circumstance, together with the subsequent restoration of Philadelphia to you, has induced me to trouble you with this letter to remind you of your kind promise of making me an accurate clock; which being intended for astronomical purposes only, I would have divested of all apparatus for striking or for any other purpose, which by increasing it's complication might disturb it's accuracy. A companion to it, for keeping seconds, and which might be moved easily, would greatly add to it's value. The theodolite, for which I spoke to you also, I can now dispense with, having since purchased a most excellent one.

Writing to a philosopher, I may hope to be pardoned for intruding some thoughts of my own tho' they relate to him personally. Your time for two years past has, I believe, been principally employed in the civil government of your country. Tho' I have been aware of the authority our cause would acquire with the world from it's being known that yourself & Doc't. Franklin were zealous friends to it and am myself duly impressed with a sense of the arduousness of government, and the obligation those are under who are able to conduct it, yet I am also satisfied there is an order of geniusses above that obligation, & therefore exempted from it, nobody can conceive that nature ever intended to throw away a Newton upon the occupations of a crown. It would have been a prodigality for which even the conduct of providence might have been arraigned, had he been by birth annexed to what was so far below him. Cooperating with nature in her ordinary economy we should dispose of and employ the geniusses of men according to their several orders and degrees. I doubt not there are in your country many persons equal to the task of conducting government: but you should consider that the world has but one Ryttenhouse, & that it never had one before. The amazing mechanical representation of the solar system which you conceived & executed, has never been surpassed by any but the work of which it is a copy. Are those powers then, which being intended for the erudition of the world are, like air and light, the world's common property, to be taken from their proper pursuit to do the commonplace drudgery of

governing a single state, a work which may be executed by men of an ordinary stature, such as are always & everywhere to be found? Without having ascended mount Sinai for inspiration, I can pronounce that the precept, in the decalogue of the vulgar, that they shall not make to themselves "the likeness of anything that is in the heavens above" is reversed for you, and that you will fulfil the highest purposes of your creation by employing yourself in the perpetual breach of that inhibition. For my own country in particular you must remember something like a promise that it should be adorned with one of them. The taking of your city by the enemy has hitherto prevented the proposition from being made & approved by our legislature. The zeal of a true whig in science must excuse the hazarding these free thoughts, which flow from a desire of promoting the diffusion of knowledge & of your fame, and from one who can assure you truly that he is with much sincerity & esteem

Your most obed't. & most humble serv't.
Thomas Jefferson

P. S. If you can spare as much time as to give me notice of the receipt of this, & what hope I may form of my clocks, it will oblige me. If sent to Fredericksburgh it will come safe to hand.

"Saugus Pot"

Joseph Jencks (1599–c. 1682) created a small cast-iron cooking pot known as the "Saugus pot" for the opening of the Saugus Iron Works of Lynn, Massachusetts (1642–1678). This modest kitchen pot symbolizes the birth of North America's iron and steel industry.

Cast from locally sourced bog-iron ore, the Saugus pot has a rounded silhouette, curving in before flaring out at the lip to support a lid. To modern eyes, the kettle shape suggests a witch's cauldron. Two handles support a bail to hang the pot above a kitchen fire, while three iron feet allow it to stand directly in the hearth coals.

Producing such a cast-iron pot required experienced ironworkers, highly skilled mold makers, and precision blacksmithing. Iron ore was smelted in a blast furnace to a paste-like consistency. Clay-sand molds were formed on a lathe using a pattern to insure consistency of shape for the interior and exterior. The hot metal was poured, or cast, into the single-use mold. A heated iron rod was hammered into the desired curve to form the bail and attached to the pot while still pliable.

Colonial kitchen pots ranged in size; some weighed up to 40 pounds when empty. The Saugus pot weighs just over two pounds and holds a quart of liquid. It was allegedly presented to Thomas Hudson

(c. 1590–1645), the original ironworks landowner, and passed through his family until it was presented to the city of Lynn in 1892. Scientific analysis in the 1950s validated the pot's origin and period of manufacture.

Iron pots and kettles were highly desired trade items and valuable possessions for colonial families. Colonists and Native Americans regarded cast-iron cookware as state-of-the-art culinary technology because it was durable and could sit directly in the fire, efficiently transferring heat to food without being destroyed.

Iron implements were vital to daily life and without a local foundry had to be imported from England. After previous failed attempts, the Saugus Ironworks was established along the Saugus River near abundant iron ore and available wood. Joseph Jencks, a master ironworker, was recruited from England to establish and operate the new facility with approximately 100 trained iron craftsmen.

Many scholars regard Jencks as America's first mechanical engineer. He was granted the first patent in the English colonies and infused the young iron industry with his prowess for technological innovation.

The Saugus foundry produced bar iron for other settlements and export as well as pots, hammers, and agricultural tools. Jencks harnessed waterpower to mechanize nail fabrication and draw wire to produce quantities of brass straight pins. Intricate sawmill blades were created for a hydropowered lumber mill running 20 simultaneous saws. Screws, bolts, and all manner of hardware (latches, hinges, locks and keys, etc.) were produced in this 17th-century state-of-the-art industrial facility.

Jencks's machine shop also invented a prototype fire engine, refined edged tools, and revolutionized scythe design. As natural resources dwindled and the Ironworks closed, Jencks and the men he trained went on to found ironworks throughout the colonies.

Within 100 years, Britain's North American colonies were the world's third-largest producers of iron. In 1750, Britain balked at the competition from its colonies, and trade acts forbid the production of iron goods. All smelted iron was required to be sent to England for formation into products. The iron industry was crushed economically, and technological advancement halted or went underground.

Foundry owners and ironworkers became early supporters of American independence. George Taylor (c. 1716–1781), Philip Livingston (1716–1778), and several other signers of the Declaration of Independence were connected to the iron industry. Taylor's foundries supplied the first cannonballs to the Continental army.

Schooner

A schooner is a sailing boat rigged with fore-and-aft sails. The foremast is shorter than the mid and aft masts. Early schooners were made with two masts, but modern schooners come in a variety of mast combinations. To be considered a schooner, a ship must have two or more masts; the front (fore) mast is shorter than the rear (aft) mast, and the mainsail is attached to the aft mast. The vessels are usually fore and aft rigged, meaning that the sails are parallel to the body. Fore and aft rigs are used mostly when the vessel is sailing a coast. Other vessels with more than one mast are usually square-rigged, meaning that they have sails that are principally positioned perpendicular to the body of the vessel. The square rig is used when going on long voyages across the ocean. Schooners were more widely used in the United States than in any other country. Steam-powered vessels caused the schooner to decline.

The schooner evolved from a Dutch fishing craft in the 1600s. Schooners originated at Gloucester,

Massachusetts. They were used in coast-wide trade where speed was necessary. Very few vessels could match the speed and versatility of the schooner. It was used as a fishing boat, and because of its speed quickly became popular among smugglers and was even used as a pirate ship and warship. In the late 19th century, the schooner was one of the most widely used cargo vessels of all time, transporting anything from coal, lumber, granite, ice, and limestone. The versatility of the schooner has been proven again and again with its capability to withstand time and the elements. The advantage of the schooner rig, because its sails run the length of the deck, is that the ship can catch the wind at a better and much closer angle. This means that it doesn't need to tack as often and can sail right into a port at closer quarters. The sails can also be used on small vessels as well as larger vessels.

Schooners were made for coastal sailing. They can deal with a variety of different wind types and do well in shallow water. The schooner was small compared to other vessels, which meant that it required a smaller crew to operate and therefore much more economical. Also, the fore and aft sails were easier to hoist up from the deck, and there was no need to have many men climb up to unfold the mast or reefing. By the beginning of the 18th century, the schooner was being used by colonial fisherman in New England because of its combination of speed, maneuverability, and economy. By the mid-18th century, the schooner became the predominant vessel for fishing and coastal trading in European waters. The ship's continued development aimed at increasing speed, allowing fishermen to catch more fish and make more money. Fisherman would race to get back to the fish auctions to get the best prices.

Also, because of its speed, the schooner became very popular with smugglers and pirates because they could get away from larger and slower British naval vessels. Shipbuilders in Maryland and Virginia modified schooners for smugglers so that they could sail into small coves. They also added square rigs on top of the mast to add extra speed. These were known as the first American-built schooners, and they were known as the "Virginia models."

Today, these ships are mostly used for private sailing and commercial party ships. Cruise lines take customers out on schooners for day trips. Schooners are

also still raced. In 1990, schooner racing began in Chesapeake Bay. The fastest sailing ship to cross the Atlantic was the schooner yacht *Atlantic*. It was built in 1903 and famously raced in 1905, crossing the ocean in 12 days, four hours, and one minute. The *Atlantic* averaged over 200 miles per day.

The schooner is considered the sturdiest wooden ship of all time. Although schooners are not used for trade today, there is some talk of reverting to wind-powered schooners in the wake of a wave of shipping company bankruptcies driven in part by the high cost of fuel.

Smallpox Inoculation

Smallpox was a deadly disease caused by the variola virus. Where it originated is unknown, but an area such as Egypt's Nile and/or India's Ganges river valleys are likely candidates, as they were densely populated enough for it easily to pass from person to person. From there, the illness probably made its way into southwestern Asia. By the 16th and 17th centuries, it had spread to most of the inhabited world, and by the end of the 18th century, smallpox had been established as a major killer, responsible for about 12 percent of all deaths and about 30 percent of deaths of urban children.

Symptoms included a high fever and a rash that turned into sores, which broke open and released more of the virus. The sores scabbed over and healed, often leaving severe scars. As many as 30 percent of survivors were left blind, and about 30 percent of victims died.

As early as the 10th century, it was noted that people who survived smallpox never caught it again. From there, a practice called “variolation” began. Named after the virus itself, variolation involved making a scratch in the skin of a healthy person and introducing material from a lesion on a patient with active smallpox, which caused a less severe form of the illness. Problems with this method included patients being just as contagious as if they had acquired the disease naturally, and nearly 2 percent of those who tried variolation died.

Variolation remained in place as the most effective means of controlling the illness until an English country doctor named Edward Jenner, though a series of observations and experiments, made a remarkable advance in the science of inoculation.

Edward Jenner was born May 17, 1749, in Berkeley, Gloucestershire, England. At the age of eight, he underwent the experience of variolation himself, which, while unpleasant, was effective (and perhaps a reason for his interest in investigating a better way to protect against smallpox). Jenner developed a strong interest in science and nature and at age 13 was apprenticed to a country surgeon in Sodbury, near Bristol. It was there that Jenner first heard a dairymaid say that she would never be a victim of smallpox because she had had cowpox, a similar but much milder illness contracted from milking cows that had an active infection on their udders. A typical case of cowpox in a human would result in sores on the hands and lower arms but was rarely if ever passed from one person to another. It was a common belief at the time that dairymaids were in some way protected from smallpox, but it would take Jenner’s later work for this to be proven true.

Upon completion of his apprenticeship at the age of 21, Jenner became the student of a well-known and respected surgeon named John Hunter, who was on the staff of St. George’s Hospital in London. Hunter passed along his expertise in experimental science, which would prove useful in many of Jenner’s later endeavors. In 1773, after two years of training with

Hunter, Jenner returned to his hometown of Berkeley to practice medicine, where he turned his thoughts once again to smallpox.

In his medical practice, he made note of people whom he inoculated against smallpox using the variolation process but who had not shown any signs of illness in response, as would normally be expected. Upon questioning, he found that these people had had cowpox, often many years earlier. He gradually compiled the evidence to support his theory that cowpox could protect against smallpox, eventually gathering a list of 31 individuals. He then set out to do a test himself.

In May 1796, Jenner found a dairymaid, Sarah Nelms, who had fresh cowpox lesions on her hands and arms. Using material from Nelms’s lesions, he inoculated an eight-year-old boy, James Phipps. The boy initially developed mild fever. Nine days after the procedure, he felt cold and had lost his appetite but had recovered by the following day. In July 1796, Jenner inoculated the boy again, this time with matter from a fresh smallpox lesion. No disease developed, and Jenner concluded that protection was complete.

Jenner continued to collect evidence and completed a second trial of his inoculation process in at least 10 people in March and April 1798. That same year, he published a paper titled “An Inquiry into the Causes and Effects of the Variolae Vaccinae, a disease discovered in some of the western counties of England, particularly Gloucestershire and Known by the Name of Cow Pox.” The Latin word for cow is *vacca*, and the cowpox virus is *vaccinia*; this is how Jenner decided to call his new procedure “vaccination.”

Jenner then set out to further publicize his procedure. In London, vaccination became popular through the activities of colleagues, some of whom he supplied with the material he used to vaccinate his own patients.

Jenner then conducted a nationwide survey to collect even more evidence that cowpox could protect against smallpox. The results of this survey confirmed his theory, and after that, vaccination spread rapidly in England. By the year 1800, it had reached most European countries.

Although he received worldwide recognition and honors, Jenner made no attempt to profit from his discovery. He devoted so much time to the cause of vaccination that his private practice suffered, and the British

Parliament, in recognition of his contribution, awarded him grant money. He continued to see patients and vaccinate poor children for most of the rest of his life. Jenner died on January 26, 1823, at the age of 73.

Primary Document: George Washington's Order for All Soldiers to Receive a Smallpox Inoculation (1778) and Letter of Edward Rowse to Thomas Jefferson Suggesting the Possibility of Vaccines for Other Diseases (1805)

The following is General George Washington's general order from March 18, 1778, ordering all soldiers who had not yet been inoculated to report to the regimental surgeon. Historians credit Washington's decision to vaccinate his troops against smallpox as one of the reasons that the Continental Army won the Revolutionary War. Also included is Edward Rowse's 1805 letter to Thomas Jefferson in which he says that the efficacy of smallpox vaccinations suggest that vaccines for other diseases might also be effective.

Head-Quarters V. Forge Wednesday March 18th 1778.

Parole: Steuben—Countersigns: Sheffield. Scarborough.

Innoculation for the Small-Pox having been happily performed on all the subjects in Camp it is necessary to guard against the fatal effects of that disorder taken in the natural way, The Commander in Chief therefore enjoins all officers commanding Regiments upon the arrival of recruits or return of absent soldiers to make immediate and strict inquiry whether they have had the Small-Pox, and order such as have not to be innoculated without loss of time by the Regimental Surgeon; and in case of the Regiments being unprovided with one to give instant notice to the Surgeon General.

The men ordered yesterday for His Excellency's guard are to parade tomorrow morning at guard-mounting on the grand-parade.

Edward Rowse to Thomas Jefferson

Boston 13th. July 1805 No. 7 Warren Street

SIR

The late discoveries in England and Turkey of the beneficial effects of the kine pox, as an effectual preventive remedy, for the diseases of the small pox, and the plague; have irresistably led me to the following reflections.

The characteristics, that belong in common to both these complaints; appear to be—a power of seizing the human species but partially; by succeeding in their attacks on some, but becoming repulsed by others—of appearing only in hot weather; with a few exceptions to the small pox—when the putrescent tendency of the fluids, is most increased by heat—and, that they are both fevers; the one eruptive, and the other putrid.

From this data; the cause of the beneficial effects of the vaccine innoculation, appears probable to be owing to some partial change of the fluids of the constitution, that the subject undergoes, approaching to the less putrefactive state of the fluids of the graminivorous animal, from whom the remedy is taken; that secures him uninjured, from the subsequent morbid attacks of these diseases; either, in inhaling an

atmosphere impregnated with their effluvia, or in an inoculation of their diseased matter.

However, as the vaccine inoculation is *proved* to be a remedy against two violent fevers—the small pox, being commonly violent, when commencing without inoculation; it is no more than reasonable to infer, that, against other fevers of a similar nature, it will produce the same effect!—And, but few will venture to assert, that the small pox and plague, are more similar, than, the plague and yellow fever!

I cannot therefore, help being of the opinion, that it is likely to prove a remedy also; for this formidable calamity of the western world.

It would give me great happiness, to become the fortunate man of accelerating the discovery of a remedy, for so great an evil.

The most satisfactory trial of it, would be, by inoculating the matter of the yellow fever on a subject, that has been prepared for it, by the vaccine inoculation; but the danger that must attend the experiment, may be considered as putting it out of the power of any one to try it, yourself alone excepted, by having the lives of condemned criminals at your

disposal.—Which necessitates me to trouble you with the affair.

I conclude it is unnecessary to send you a detail of the effects of the vaccine inoculation against the plague, as it has passed into most of the papers of the States.

I shall be obliged to you to inform me whether you think favorably enough of it, to induce you to give it a trial. You will also much increase the obligation, by informing me of the present condition of the breed of Arabian horses in Virginia; and to what degree they have arisen, as an article of comm[erce?] since the account you published of them, in your Notes on that State: And of the original stock was imported from south Arabia.

With the highest esteem, I have the honor to be
Sir, your most obedient Servant
EDWD ROWSE

Spinning Wheel

The exact origins of the spinning wheel, a device used to turn natural fibers into usable thread, are unknown, but the apparatus that would be recognizable as the spinning wheel in use in early America appears to go back to 13th-century Europe. The first forerunner to the wheel was the handheld spindle, a tool that appears to have originated in India as early as 500 BCE. Today, many modern spinners first learn to turn fiber into yarn with a handheld spindle.

While the spinning wheels in use through history have varied in style depending upon the area of the world in which they were used, the basic mechanism remained the same: raw fiber was held on a spindle that was turned by a mechanism powered by a large wheel operated by a person called the spinner. As the fiber came off the turning spindle, the spinner manipulated it, twisting the strands into yarn that was then woven into fabric. Improved versions of the spinning

wheel included a foot-operated treadle, leaving both of the spinner's hands free. Variations in wheel designs made them suitable for different fibers; flax required a different wheel from wool and cotton, which could both be spun on the same style of wheel.

The spinning wheel was ubiquitous in the early American household. In that era of gender-specific work roles, women and girls spun the yarn, while loom operation was considered a man's job. At that time, the term "spinster" was a compliment, as a "spinster" connoted a woman who spun with great skill and productivity. As the essential partner to her husband, the "goodwife" was expected to be a proficient, if not expert, spinster.

The spinning wheel is historically significant in America for a number of reasons. First, it allowed early colonists to cover and clothe themselves at a time when manufactured fabrics were unavailable or prohibitively expensive. It also represents the importance of "women's work," of which spinning was only one essential part. In

While the phrase “spinning wheel” conjures up images of a one-wheeled apparatus, the water- or steam-powered factory spinning wheel, invented by Richard Roberts in 1825, revolutionized textile production. Textile factories also changed the way workers interacted with their product, transforming skilled workers into low-waged, unskilled workers. (Ann Ronan Pictures/Print Collector/Getty Images)

addition, the manual spinning of fiber into thread was a forerunner of the American textile industry, which emerged in the post-Revolutionary era.

Early American colonists manufactured most of their textiles at home. The making of fabric involved a bewildering number of steps, beginning with the cultivation of the plant or animal that provided the fiber. In the earliest period, women most often worked with fibers produced from the flax plant. At that time, settlers were still in the process of clearing land and eliminating predators to prepare for the farming of sheep. Only with the arrival of sufficient numbers of sheep in the colony could colonists begin to produce woolen yarn for textiles. Cotton spinning did not commence in great volume until after 1793 and the invention of the cotton gin. While the production of all fibers was complicated and time-consuming, the cost and limited

availability of imported fabrics made their purchase prohibitive for the majority of colonial Americans.

As the colonies developed and imported textiles became more readily available and affordable, women began to drift away from the spinning wheel, and its importance diminished. The American Revolution and the advent of boycotting and nonimportation agreements prompted the resurgence of interest in spinning and home manufacture of textiles, encouraging women to get their old wheels down from the attic. Some women’s groups even provided classes for younger ladies and girls who had grown up at a time when spinning was no longer a required art; others spun thread, produced cloth, and sewed shirts for Continental soldiers.

The end of the Revolutionary War marked the demise of the mercantile system, the prohibition of finished goods for trade, and consequently the beginning

of the textile industry in the United States. Power thread and textile mills replaced hand spinning and weaving. In 1793, Samuel Slater built the first American mill for spinning thread, and by 1821, the famed mill town of Lowell, Massachusetts, had begun production of textiles. The Slater and Lowell mills represent only two of the numerous textile mills in operation in the United States by the 19th century. Encouraged by Eli Whitney's 1793 invention of the commercially viable cotton gin, cotton culture expanded in the South, hand in hand with more efficient and cost-effective production of cotton yardage in the Northeast.

The spinning wheel's use in the American colonies helped to sustain colonists' ability to clothe themselves, promoted patriotism during the Revolutionary War, and

supported the establishment of trade industry in the Early Republic. Its descendant, the power textile mill, firmly established the textile industry in the 19th century, further solidifying the United States' role in international trade and strengthening the American economy.

Primary Document: An "Address to the Ladies" Urging American Women to Boycott British Goods (1767)

The spinning wheel became a significant symbol of the American Revolution as women rejected British-made textiles and urged those with a revolutionary bent to spin and weave their own cloth as part of a nonconsumption movement. The "Address to the Ladies" seen here appeared in Boston newspapers in 1766 and 1767 to encourage women to boycott British goods and wear homespun fabrics, highlighting the political importance of the spinning wheel.

Address to the LADIES.

*Young ladies in town, and those that live round,
Let a friend at this season advise you:
Since money's so scarce, and times growing
worse
Strange things may soon hap and surprize you:
First then, throw aside your high top knots of
pride
Wear none but your own country linnen;
of Oeconomy boast, let your pride be the most
What, if homespun they say is not quite so gay
As brocades, yet be not in a passion,
For when once it is known this is much wore
in town,*

*One and all will cry out, 'tis the fashion!
And as one, all agree that you'll not married be
To such as will wear London Fact'ry:
But at first sight refuse, tell'em such you do
chuse
As encourage our own Manufact'ry.
No more Ribbons wear, nor in rich dress appear,
Love your country much better than fine things,
Begin without passion, 'twill soon be the
fashion
To grace your smooth locks with a twine
string.
Throw aside your Bohea, and your Green
Hyson Tea,
And all things with a new fashion duty;
Procure a good store of the choice Labradore,
For there'll soon be enough here to suit ye;
These do without fear and to all you'll appear
Fair, charming, true, lovely, and cleaver;
Tho' the times remain darkish, young men may
be sparkish.
And love you much stronger than ever. !*

Street Lighting

Street lighting in towns and cities dates to the mid-1600s. Benjamin Franklin designed and oversaw the installation of streetlights in Philadelphia in 1757. Cities in the American colonies such as Boston, Philadelphia, and New York already had streetlights, but Franklin's design is generally considered a great leap forward in street lighting technology. Electric streetlights first appeared in 1889 and are now widely used in American towns and cities.

Cordova, in the Moorish territory in Spain, was the earliest city to have fixed streetlights with candles in the mid-17th century, followed by London in the early 18th century. Within a few decades, they were available in the major cities of the American colonies. The earliest colonial era streetlights were lit by candles placed inside a glass vessel, which kept the candle from being blown out by wind.

Although Franklin was not the first to propose street lighting, he materially improved the old London globes that were used for lighting streets at that time. On March 9, 1756, the Pennsylvania Assembly passed Franklin's bill for providing night watchmen and street lighting for Philadelphia. In his autobiography, Franklin credits another Philadelphian, John Clifton, for introducing the utility of streetlights by being the first to place one outside his door. They were sometimes hung from buildings or poles in the streets or on pumps. By 1767, there were 320 lamps for a population of 26,000 living in Philadelphia. The fines for breaking such lamps grew from 40 shillings in 1751 to £20 via the Act of 1771.

Franklin designed a lamp of four flat panes with a funnel above to draw up the smoke, and crevices admitting air below to assist the ascent of the smoke. This way, they were kept clean and did not go dark in a few hours, as the London globe lamps did. Additionally, when there was an accident, instead of replacing the whole globe, only a single pane had to be replaced. The new whale oil streetlights also kept the streets illuminated much longer, helping to dramatically reduce murder rates in Philadelphia. Franklin mentioned these innovations to Dr. John Fothergill, an English physician and scientist, who had earlier

written a preface to Franklin's writings on electricity. Reproductions of the Franklin lamp are still in use today around Independence Hall and other museums in Philadelphia.

With the invention of gaslights by William Murdoch in 1792, more cities in Europe began lighting their streets, gas being both cheaper and brighter than candles. In 1816, Baltimore was the first American city to use gaslights to light its streets. Gaslights remained popular throughout the 19th century in the United States. Thomas Edison pioneered the electric lightbulb, which considerably improved streetlight technology. On March 31, 1889, Wabash, Indiana, became the first electrically lit city in the world. Fluorescent and incandescent lights grew in popularity in the 1930s and 1940s and were made mostly by General Electric and Westinghouse.

Swim Fins

Benjamin Franklin was associated with many inventions—but his first was a pair of swim fins, which he invented when he was 11 years old. Growing up in Boston, Franklin loved the water—specifically the Charles River, the Atlantic Ocean, and Boston Harbor, and he often dreamed of becoming a sailor. He learned to swim by himself and also taught his playmates, using the fins in the pond in Boston Common. He later used kites, and holding one aloft, he floated on his

back and let it pull him. He had another boy carry his clothes to the other side of the pond while he swam across it using his fins and kite.

Franklin's first lessons in swimming were from one of the first books on the subject, *The Art of Swimming*, written in 1696 by Melchisedec Thevenot, a Frenchman, who helped popularize the breaststroke. Franklin toyed with ways to make himself go faster. He observed that the limit to how much water one could push and hence one's propelling power was a function of the size of one's hands and feet. To increase his speed while swimming, he devised fins that he wore on his hands. They were made of wood and were oval, like lily pads or an artist's paint palette, and helped the swimmer attain greater speed with each stroke. They were roughly 10 inches long and about 6 inches wide, and they had a circular opening where the thumb could be placed to hold on to the pad. He also fitted the soles of his feet with a kind of swimming sandal. In 1773, Franklin wrote about his first invention, noting that while the fins did increase his speed, they fatigued his wrists. He was also unhappy with the foot fins, noting that the inside of the foot was as important in swimming as the sole.

While living in London, Franklin used his fins while swimming a few miles in the Thames River. He considered opening a school for the instruction of swimming in the city but decided against it. In his 1749 essay, "Proposals relating to the education of youth in Pennsylvania," he proposed swimming be a part of the curriculum, an unheard-of idea in the 18th century. One of the people he taught to swim in London was a fellow young printer named Wygate, who proposed that the two of them travel around Europe as journeymen printers and swimming instructors. Franklin considered the idea but was persuaded by Thomas Denham, a Quaker merchant, to return to Philadelphia and serve as his clerk for £50 a year.

Franklin's first invention did not really catch on with the American or European publics, who regarded swimming with great skepticism. Swim fins are popular today—modern versions have been created for paddle boarding and body surfing as well as for competitive swimming practice. Franklin's advocacy for swimming was recognized over two centuries later when he

was inducted into the International Swimming Hall of Fame in Fort Lauderdale, Florida, in 1968.

Three-Wheel Clock

Ben Franklin invented a 24-hour, three-wheel clock, which was much simpler than the typical clock designs of the time. This clock, like others in the 18th century, had only an hour hand. Minute hands were added to clocks much later.

Franklin did not write a description of the clock that he had devised. James Ferguson (1710–1776), an astronomer, mathematician, and horologist who had also published Franklin's magic squares and magic circles, published a design for the clock in 1773, probably unbeknown to Franklin at the time. When Franklin discovered Ferguson's improvements, he was delighted. The clock was often called "Ferguson's clock" and was an improvement on a single handed clock that Franklin had invented and was known as "Franklin's clock."

Ferguson credited Franklin for creating a clock showing hours, minutes, and seconds and having only three wheels and two pinions in the whole movement. The hours were engraved in spiral spaces along two diameters of a circle containing four times 60 minutes.

The clock could operate for up to 30 hours at a time. Ferguson noted that several clocks had been made according to Franklin's specifications and that they measured time remarkably well. He, however, pointed out two limitations in Franklin's version of the clock: a) it required rewinding more than once a week, and b) the

hand of the clock could not be upon any hour without being over four hours at the same time. He modified the clock by having only the minutes of one hour shown on the single dial, and small segments of revolving plates, set behind the dial and bearing numbers for the hours and seconds, appeared through small apertures in it.

He showed it to Franklin, who approved of the alterations. Ferguson also devised a clock showing motions of the sun and moon and the times of high and low tide. Franklin had John Whitehurst of Derby, England, construct clocks for him on these designs.

Three-wheel clocks still exist today, both centuries-old originals and as reproductions.

Primary Document: James Ferguson's Description of Benjamin Franklin's Three-Wheel Clock (1773)

Astronomer and mathematician James Ferguson published a description of Benjamin Franklin's three-wheel clock in 1773, in great part because Franklin did not do so himself. The three-wheel clock was regarded as a great improvement on single-wheel clocks.

A Clock shewing the Hours, Minutes, and Seconds, having only three Wheels and two Pinions in the whole Movement. Invented by Dr. FRANKLIN of Philadelphia.

The dial-plate of this clock is represented by Fig. 1. of Plate I. The hours are engraven in spiral spaces, along two diameters of a circle containing four times 60 minutes. The index *A* goes round in four hours, and counts the minutes from any hour it has passed by, to the next following hour. The time, as it appears in the figure, is either 32½ minutes past XII, or past IIII, or past VIII; and so on in each quarter of the circle, pointing to the number of minutes after the hours the index last left in its motion. Now, as one can hardly be four hours mistaken in estimating the time, he can always tell the true hour and minute, by looking at the clock, from the time he rises till the time he goes to bed. The small hand *B*, in the arch at top, goes round once in a minute, and shews the seconds as in a common clock.

Fig. 2. shews the wheel-work of this clock. *A* is the first or great wheel, it contains 160 teeth, goes round

in four hours, and the Index *A* (Fig. 1.) is put upon its axis, and moved round in the same time. The hole in the index is round, it is put tight upon the round end of the axis, so as to be carried by the motion of the wheel, but may be set at any time to the proper hour and minute, without affecting either the wheel or its axis. This wheel of 160 teeth turns a pinion *B* of 10 leaves; and as 10 is but a 16th part of 160, the pinion goes round in a quarter of an hour. On the axis of this pinion is the wheel *C* of 120 teeth; it also goes round in a quarter of an hour, and turns a pinion *D*, of 8 leaves, round in a minute; for there are 15 minutes in a quarter of an hour, and 8 times 15 is 120. On the axis of this pinion is the *second-hand B* (Fig. 1.) and also the common wheel *E* (Fig. 2.) of 30 teeth, for moving a pendulum (by pallets) that vibrates seconds, as in a common clock.

This clock is not designed to be wound up by a winch, but to be drawn up like a clock that goes only 30 hours. For this purpose, the line must go over a pulley on the axis of the great wheel, as in a common 30 hour clock. Several clocks have been made according to this ingenious plan of the Doctor's, and I can affirm, that I have seen one of them, which measures time exceedingly well. The simpler that any machine is, the better it will be allowed to be, by every man of science.

Turtle Submarine

The *Turtle*, named for an appearance similar to its namesake, was the world's first submersible with a documented record of use in combat. It was deployed by the Continental Army in 1776 to attack British ships in New York Harbor during the American Revolution. Although the attack failed, the world was put on notice that naval warfare would no longer be confined to the water's surface.

The *Turtle* was the brainchild of David Bushnell, a Yale University student. Bushnell equipped the *Turtle* to dive by flooding a compartment with water, and then to surface by forcing the water out by using a hand pump. The underwater craft featured propellers to allow it to travel up and down as well as backward and forward, reaching speeds of nearly three miles per hour. Built from sturdy wood that was sealed with tar to prevent leaks, and internally braced by a heavy steel ring, the *Turtle* was 6 feet high, 10 feet long, and 3 feet wide. Lighting was provided by six small pieces of glass, and air entered the chamber through two snorkels until the craft slipped below the surface. Once it was submerged, there was enough air for a 30-minute mission, and in the darkness the directional gauges were illuminated by bioluminescent foxfire.

But what made the *Turtle* lethal was its weapons package. It carried a time bomb attached to its hull, which could be secured to an enemy ship. A clockwork mechanism would allow the sub to leave the area before the explosion was triggered.

The *Turtle* saw its first and only action on the night of September 6, 1776, when it entered New York Harbor with orders to destroy the HMS *Eagle*, the flagship of British Admiral Richard Howe. Howe's squadron had taken control of the harbor and was protecting British forces coming ashore. Ezra Lee, a sergeant in the Continental Army, was piloting the *Turtle* and spent most of the evening trying to get close enough to the *Eagle* to attach his explosive charge, but without success. As dawn approached, and fearing detection, Lee broke off the attack but was discovered by British sailors, who gave chase in a rowboat. He jettisoned the time bomb, which exploded; the resultant commotion provided the diversion he needed to escape. But escape was only temporary. The following month, British warships attacked and sank the tender ship carrying

The iconic *Turtle* was the first submersible craft used in combat. David Bushnell built the *Turtle* in 1775 to attach explosive charges to British ships in the New York harbor. Bushnell's submersible craft failed to sink any ships, but it began the race to build a working military submarine. (Drawing courtesy of John Batchelor/Department of the Navy)

the *Turtle*. Bushnell reportedly salvaged what was left of his submarine, but no one knows for sure what happened next. News of its return to the Revolutionary War never surfaced, and Bushnell spent the rest of the conflict building exploding mines that could be floated out to sea to attack British ships. Anyone interested in seeing what the *Turtle* looked like can see a life-size replica at the Submarine Force Library and Museum in Groton, Connecticut.

Primary Document: Letter of David Bushnell to Thomas Jefferson Regarding Bushnell's Experiments with Submarines (1787)

Described by George Washington as an "effort of genius," the Turtle submarine was designed to break the British blockade of the colonies. Though its military contributions were minimal, it was nonetheless the world's first combat submersible. In 1787, David Bushnell, inventor of the submarine, and Thomas Jefferson exchanged letters about the Turtle. Bushnell wrote a long letter explaining both how the machine was constructed and how it responded to testing. The excerpt here is about experiments that Bushnell conducted.

"Experiments made to prove the nature and use of a Submarine Vessel."

No.3.

The first experiment I made, was with about two ounces of gunpowder, which I exploded four feet under water, to prove to some of the first Personages in Connecticut, that powder would take fire under water.

The second experiment was made with two pounds of powder, inclosed in a wooden bottle, and fixed under a hogshhead, with a two inch oak plank between the hogshhead and the powder; the hogshhead was loaded with stones as deep as it could swim; a wooden pipe descending through the lower head of the hogshhead, & through the plank into the powder contained in the bottle, was primed with powder. A match put to the priming exploded the powder, which produced a very great effect, rending the plank into pieces, demolishing the hogshhead, and casting the stones and ruins of the hogshhead, with a body of water many feet into the air, to the astonishment of the spectators. This experiment was likewise made for the satisfaction of the Gentlemen abovementioned.

I afterwards made many experiments of a similar nature; some of them with large quantities of powder; they all produced very violent explosions, much more than sufficient for any purpose I had in view.

In the first essays with the submarine Vessel, I took care to prove its strength to sustain the great pressures of the incumbent water when sunk deep, before I trusted any person to descend much below the surface: and I never suffered any person to go under water without having a strong piece of rigging made fast to it, until I found him well acquainted with the operations necessary for his safety. After that I made

him descend and continue at particular depths, without rising or sinking, row by the compass, approach a Vessel, go under her, and fix the Woodscrew, mentioned in No 2, and marked A, into her Bottom, &c. until I thought him sufficiently expert to put my design into execution.

I found agreeably to my expectation, that it required many trials to make a person of common ingenuity, a skilful operator. The first I employed was very ingenious and made himself master of the business, but was taken sick in the campaign of 1776 at N.York, before he had an opportunity to make use of his skill, and never recovered his health sufficiently afterwards.

Experiments made with a submarine Vessel.

After various attempts to find an operator to my wish, I sent one, who appeared more expert than the rest, from N. York to a fifty gun Ship lying not far from Governour's Island. He went under the Ship and attempted to fix the Woodscrew into her bottom, but struck as he supposes, a bar of iron, which passes from the rudder hinge and is spiked under the Ship's quarter. Had he moved a few inches, which he might have done without rowing, I have no doubt, but he would have found wood, where he might have fixed the screw; or if the Ship were sheathed with copper, he might easily have pierced it: but, not being well skilled in the management of the Vessel, in attempting to move to another place, he lost the Ship. After seeking her in vain, for sometime, he rowed some distance, and rose to the surface of the water, but found daylight had advanced so far, that he durst not renew the attempt.

He says that he could easily have fastened the Magazine under the Stern of the Ship, above water, as he rowed up to the stern, and touched it, before he descended. Had he fastened it there, the explosion of one hundred and fifty pounds of powder, the quantity contained in the Magazine, must have been fatal to the Ship. In his return from the Ship to N. York, he passed near Governor's Island, and thought he was discovered by the Enemy, on the Island; being in hast to avoid the danger he feared, he cast off the magazine, as he imagined it retarded him, in the swell, which was very considerable. After the Magazine had

been cast off, one hour, the time the internal apparatus was set to run, it blew up with great violence.

Afterwards there were two attempts made in Hudson's River above the City, but they effected nothing. One of them was by the aforementioned person. In going toward the Ship, he lost sight of her, and went a great distance beyond her, before he found her; when he arrived, the tide ran so strong, that as he descended under water, for the Ship's bottom, it swept him away. Soon after this, the Enemy went up the river, and pursued the boat, which had the submarine Vessel on board, and sunk it, with their shot. After I recovered the Vessel, I found it impossible, at that time to prosecute the design any farther. I had been in a bad state of health from the beginning of

my undertaking, and was now very unwell; the situation of public affairs was such, that I despaired of obtaining the public attention, and the assistance necessary. I was unable to support myself, and the persons I must have employed, had I proceeded. Beside I found it absolutely necessary, that the operators should, acquire more skill in the management of the Vessel, before I could expect success; which would have taken up sometime, and made no small additional expence. I therefore gave over the pursuit, for that time, and waited for a more favourable opportunity, which never arrived.

Whiton, David Erskine (1825–1904)

David Erskine Whiton was an inventor and manufacturer. His name was familiar to machinists and craftsmen in the 19th century due to the popularity of machine tools bearing his name. In later years, the company he founded moved into the creation of steam turbines for naval vessels.

Whiton was born in Stafford, Connecticut, in 1825. After only a few years, Whiton left school, spending the rest of his youth as a carpenter's apprentice. He went west as a young man, settling briefly in Wisconsin before returning to Stafford. There, he opened a shop and went to work as a millwright. One of his most important products was a turbine-based waterwheel of his own design, but Whiton found his greatest success as a by-product of this business.

To accurately and quickly create turbine shafts, Whiton's shop relied on a centering machine that he'd created. It rapidly drilled and reamed steel shafts of various diameters, dramatically improving the productivity of machinists in many industries. In 1856, Whiton filed for a patent on his centering machine; the Whiton Centering Machine was soon found in machine shops across the country. Whiton received patents for several other machine tools and expanded his line of business into lathes and chucks—undramatic but essential tools in any machine shop. He also introduced improved gear-cutting machines. These devices

allowed machinists to quickly and accurately create gears to replace worn or damaged ones. Whiton's innovations improved the quality and speed of machining in countless small shops and large factories.

In 1886, the Whiton Machine Company moved to New London, Connecticut, to take advantage of the city's port and larger labor pool. While machine tools remained a vital part of his business, Whiton's expertise with turbines and the Whiton Company's new coastal location meant that he could become intimately involved in New London's thriving shipbuilding industry. Whiton centering machines were used to machine shafts for large naval turbines as well as for steam locomotives and later for automobiles and airplanes.

Whiton remained an active member of his community while running his business; he served in a number of elected positions. He served two terms as a state representative, representing his hometown of Stafford. Upon his death in 1904, he was succeeded as president of the Whiton Machine Company by his son, Lucius.

The Whiton Company long outlived its founder, remaining an independent company until 1970. It continues in operation today as part of Dresser-Rand, a division of the large German conglomerate Siemens. Its turbines power a large number of naval vessels, most notably the nuclear submarine fleet of the U.S. Navy.

Winthrop, John (1714–1779)

John Winthrop, astronomer, physicist, and mathematician, was a fifth-generation descendant of Governor John Winthrop, founder of the Massachusetts Bay Colony. He served as Hollis Professor of Mathematics and Natural Philosophy at Harvard College from 1738 until his death in 1779. He was an accomplished scientist and preeminent American astronomer, whose observations on natural phenomena revolutionized colonial science and science education.

John Winthrop was born in Boston, Massachusetts, in 1714 to Judge Adam Winthrop and Anne Wainwright Winthrop. He entered Harvard at age 13 and graduated in 1732. He continued his studies and earned an AM in 1735. Once a professor at Harvard, Winthrop introduced his students to Newtonian principles of natural law. He created the first experimental physics laboratory in 1746, becoming the first professor to demonstrate the properties of electricity in a classroom, and he introduced elements of calculus to the Harvard curriculum in 1751. In 1746, he married Rebecca Townsend, with whom he had five sons.

Winthrop's cemented his reputation as America's foremost astronomer through the study of many astronomical phenomena. In 1740, he observed the transit of Mercury across the face of the sun, detailing the planet's movement. His findings, along with his observations on a lunar eclipse, were published in the Royal Society of London's *Philosophical Transactions*, the most prominent science journal of the time. He would publish 10 additional articles in the serial over the course of his career. In 1761, under orders from

Massachusetts Bay governor Francis Bernard, Winthrop led Harvard's first scientific expedition, a trip to St. John's in Newfoundland, Canada, to observe the rare transit of Venus. Despite swarming insects and threatening weather, Winthrop and two of his students made the only successful observations of the transit in North America.

Winthrop also had a great interest in natural phenomena. On November 18, 1775, he recorded detailed observations of an early-morning earthquake. In his account for the Royal Society of London, he correctly posited that earthquakes produce simultaneous horizontal and vertical movement, although he falsely asserted that earthquakes were caused by chemical explosions within the earth. His hypotheses placed him in opposition to prominent clergymen, including Boston minister Thomas Prince, who preached that earthquakes were manifestations of God's wrath. Winthrop published a second pamphlet, *Answer to Mr. Prince's Letter on Earthquakes*, in 1756 in response to Prince's claims. That same year, he married his second wife, Hannah Fayerweather Tolman.

Winthrop was elected a fellow of the Royal Society in 1766, thanks to support from Benjamin Franklin. He was named a fellow of the Harvard Corporation and received Harvard's first honorary LLD in 1774. He was active in public affairs, serving on the Massachusetts Bay Council in 1773–1774, and became a member of the Massachusetts Provincial Congress during the American Revolution. After the battles of Lexington and Concord on April 19, 1775, Winthrop rescued the college library and scientific instruments, moving them to Andover. He died in Cambridge, Massachusetts, on May 3, 1779.

Primary Document: John Winthrop Describes His Observation of the Planet Venus (1761)

Colonial Americans were fascinated by comets and by astronomy. Many astronomers began their studies looking for comets and discovered other astronomical phenomena. In the excerpt here, John Winthrop describes his 1761 observation of Venus at St. John's, Newfoundland. Winthrop would publish an account of his discoveries in the Philosophical Transactions of the Royal Society.

The town of St. John's being bounded with high mountains toward the Sun-rising, so that no house in it would answer our end, we were obliged to seek farther, and after a fatiguing and a fruitless attempt or two fix'd on an eminence at some distance, from whence we could have a view of the Sun presently after his rising. As this place was open and had no building near it, we pitch'd some tents upon it for a shelter, which, together with our Apparatus and such materials as we had occasion to make use of, we convey'd up thither with the labor of several days. We secured the Clock to a pillar set in the ground under a large tent. Near this tent and within call of the Clock we fix'd two others firmly in the ground: one, to mount the refracting telescope upon; the other, which was above 8 feet high, for a Style, having at top a plate of lead with a little hold for transmitting the

Sun's rays; and we laid a large horizontal Platform on the ground to receive these rays. This Platform we kept cover'd to defend it from the Sun and the weather, and examin'd its position every time we made use of it by a very long level. On this we carefully traced a meridian line, by correspondent altitudes of the Sun, taken both with the Reflector and by the Sun's image on the Platform. And, in order fully to examine and verify the meridian and adjust our clock, we repeated these operations every fair day, and many times in a day, and continued them with an assiduity which the infinite swarms of insects, that were in possession of the hill, were not able to abate, tho' they persecuted us severely and without intermission, both by day and by night, with their venomous stings. It would be tedious, as well as needless, to give a detail of the observations we made with this intent: 'Tis sufficient that we regulated the clock with as much exactness as we could have done at home. Thus prepared, we waited for the critical hour, which proved favorable to our wishes.

2. The New Republic and the Market Economy (1780–1820)

OVERVIEW

Winning the Revolutionary War (1776–1781) jolted the American psyche. Farmers, craftspeople, and merchants had won independence from a ruling European monarch. The people of the United States of America had created a new country, but to join the global community of nations, they needed to invent their future.

Political freedom sowed national confidence; all things seemed possible. The nation's colonial past nurtured an innovative spirit, but disparate religious and political attitudes dismissed science. Before the country could build a future, attitudes toward science would need to evolve. An important step was establishing a strong foundation based on a factual understanding of the country's assets. The first national scientific effort was to collect population, economic, and geographical data.

Over the next 40 years, science and technology initiated major changes across the young nation; an agricultural colony dependent on imported manufactured goods transformed into a developing industrial powerhouse exporting products and ideas to the world. “Change” was the key word as America plunged into the market economy.

The Significance of American Immigration

Unintentionally, the colonial period created the perfect incubator for ingenuity. The distance between North America and its colonial rulers empowered colonists to prevail on their own. Without the controlling oversight of European craft guilds, knowledge was more freely exchanged, and immigrants from a range of countries and backgrounds contributed diverse skills and talents. Dutch sawmill design integrated with innovative English ironwork at the Saugus Iron

Works under Joseph Jencks (1599–c. 1682) to produce an American water-powered sawmill with 20 simultaneously running iron saw blades. German, Irish, and Scottish weaving methods combined with English looms to create American textiles.

African technologies for growing rice and producing pottery were assimilated into Southern plantation culture through enslaved Africans. Slaves, imported through the Caribbean, contributed knowledge of cultivating and processing indigo. Some enslaved individuals who had fought in the Revolutionary War were offered their freedom. Free people of color added their voices to the mix of ideas.

With the war's conclusion, many French, British, Scottish, and Hessian soldiers stayed to participate in America's opportunity. They brought European technological experience and helped invigorate the iron and mining industries. Immigrants to America frequently arrived with expertise in one trade, only to reinvent themselves in another. English weavers became farmers. Ironworkers became mechanics—designers of machinery. Benjamin Franklin (1706–1790) was a printer and author turned statesman and scientist. He learned fluidity of profession from his father, an English wool dyer who transformed himself into a soap and bayberry candle maker. In true American form, Charles Willson Peale (1741–1827) apprenticed in the leather trade, worked as a silversmith, and repaired clocks before becoming a successful portrait painter with the time and finances to explore his interests in natural history.

Political and Religious Attitudes toward Science

As early as 1743, the American Philosophical Society (APS) in Philadelphia, Pennsylvania, and activist

individuals like Franklin and Peale, had begun nurturing the seeds of scientific inquiry. But after a century of colonial existence, the infant country had little scientific or technological infrastructure. There were no schools of higher education in medicine, engineering, architecture, theoretical mathematics, or physical science. Americans lacked science education, but they approached problem solving with broad insight, varied experience, and flexibility.

Before the United States could embrace science and transformative technology, it had to address two philosophical hurdles: religious beliefs and political ideals.

Many early immigrants to the British colonies were religious refugees. Despite their own persecution in Europe, most groups established insular townships intolerant of other religious beliefs. Unifying Catholic Maryland, Puritan Massachusetts, Quaker Pennsylvania, Anglican Virginia, and Jewish communities in New York and South Carolina required a commitment to religious tolerance and freedom of worship. Unlike most European countries, which followed the religions and worldviews of their kings or queens, religious philosophy in the United States varied regionally.

In New England, Puritan Christianity impacted daily life, local government, and the first schools of higher education. Harvard College (founded in 1636; now Harvard University) and Yale College (founded 1701; now Yale University) were founded to train ministers and civic leaders. Eventually, these schools provided a rounded liberal arts education for the ideal gentleman, but even in 1780, this did not include physical science or theoretical math. Puritan “natural theology” supported identifying the general “laws of nature” to provide evidence of God as an intelligent creator. They believed that weather proved God’s informed manipulation of the environment; severe storms were God’s punishment. Such a worldview had limited use for scientific investigation.

Quaker religious philosophy emphasized a personal search for God in the physical world, a view that aligned with scientific inquiry. The Quakers believed that understanding nature could empower inventive individuals to improve life for everyone. Charting weather data enabled prediction of weather patterns, which could be published in almanacs to benefit

farmers and sailors. William Penn’s Quaker colony established the first fertile ground for science in the British colonies. Under Franklin’s leadership, the College of Philadelphia (founded 1756; now the University of Pennsylvania) was the first North American college to teach science in the form of natural history. With the exception of Pennsylvania’s, science in the colonies struggled and remained decades behind Europe’s.

Political beliefs also impacted science. In America, knowledge for its own sake had few champions. Most people spent their days producing for their daily needs or laboring to support themselves. A hardworking populace had proudly banished British aristocracy. In Europe, aristocrats and wealthy individuals pursued scientific endeavor at their leisure. Many Americans considered studying science undemocratic. Even the Quakers valued knowledge mainly for its practical uses. In a young America, college professors were expected to teach students, not waste time on research.

European governments or monarchs occasionally financed scientific inquiry, but the new American central government was too tenuous and underfunded. It would take 20 years and a president with a scientific background, Thomas Jefferson (1743–1826), before the U.S. government would financially support scientific investigation.

The Nation’s Foundation

American industry had been actively suppressed by Britain before the war. Most people, even the Founding Fathers, rarely traveled outside their home colony. Trade between colonies had been banned to maintain Britain’s monopoly on manufactured goods. Alexander Hamilton’s *Report on the Subject of Manufactures* (1791) revealed that most manufactured products in the new country were produced by resident craftspeople for local consumption.

Across all states, agriculture continued to be Americans’ dominant occupation. Most families produced food for themselves with marginal surpluses sold locally. In the South, a small but affluent agrarian society grew cash crops—tobacco, rice, indigo, and pine products—subsidized by the labor of enslaved African people. In 1780, as independent minds forged the new democratic government, they also collected practical

data on their new nation. The American Academy of Arts & Sciences (1780–) was established in Cambridge, Massachusetts, to support research and provide factual information to government policy makers.

Shipbuilding was the primary established industrial technology. Sailing ships or animal-drawn carriages provided most transportation. Wood supplied energy for cooking and heating. Small industrial enterprises, like sawmills or gristmills (processing grain), were powered by water, wind, or domestic animals on treadmills.

To determine the country's population, President George Washington (1732–1799) signed the 1790 Census Act. Much to his surprise, the census enumerated only 3.9 million people across the 13 states and four territories. The majority of citizens were of European descent or “white”; however, these individuals had come from a range of social backgrounds, religious views, and ethnic traditions. Fewer than 60,000 were free people of color. Over 694,000 individuals, or 18 percent of the population, were enslaved people, primarily from Africa.

While social and political change marked the early years of the United States, the success of the democratic experiment depended on economic transformation. An insular agrarian society dependent on imported manufactured goods needed to become a self-sufficient innovator and producer. The first step required was the public sharing of ideas. Incremental technological advances needed to be captured and built upon. During the Revolutionary War, Peale and astronomer David Rittenhouse (1732–1796) had worked together on a telescopic rifle sight. Ultimately, they were unsuccessful, and Peale only documented brief notes on their work in his diary. Throughout the colonies, individuals or workshops may have experimented with mechanical devices or scientific questions, but little was written down. Most innovators worked while ignorant of what others were creating. That was about to change.

Just as a committee had written the Constitution, dynamic technological growth in America occurred when many minds worked together or in competition. Scientific advances seldom bloomed in the hands of individual geniuses. The greatest American innovators were creative tinkerers who shared their successes and

failures and built on their discoveries. All citizens were asking: How could everyday life be made better? Science and technology were transforming all sectors of society: agriculture, industry, medicine, construction engineering, transportation, and energy.

Agricultural Innovation in the New Republic

Agriculture was initially reluctant to embrace new ideas. Land was fertile and abundant; farmers could produce enough to feed their families with reasonable surpluses. Change seemed unnecessary. Both Jefferson and Charles Newbold (1780–unknown) designed plows to increase agricultural efficiency, but neither was readily accepted. Farmers feared that Newbold's cast-iron plow would poison the soil.

Inventive farmers made slight plow modifications, but the motivation to increase crop production was not driven by farmers. Oliver Evans's (1755–1819) mechanized flour mill reduced the cost of producing flour and flour-based foods. To fill the growing consumer demand, farmers were propelled toward farm industrialization, mass-producing a single crop for sale.

As a young man, Oliver Evans (1755–1819) apprenticed in a wheelwright's workshop and often discussed ideas with his brothers. He combined gears and conveyor belts, turn-screws, and waterpower to design the first automated factory—a mill for grinding wheat kernels into flour. His automated mill functioned with minimal human supervision, greatly reducing manpower, and it tripled flour production. Eliminating human handling of wheat during processing reduced contamination and improved food safety.

Not only did Evans revolutionize flour production, to promote his design, he published his technical drawings in *The Young Millwright and Miller's Guide*. It became one of America's first accessible publications documenting a technological advance. Other inventive thinkers could examine Evans's ideas in detail. In 1790, when the federal government established the U.S. patent system, Evans's automated flour mill became American Patent No. 3. The U.S. patent system enabled creative men or women, of any ethnicity, to register an invention and legally protect their intellectual property. Technological advances and ideas were officially documented.

President Washington toured the countryside, visiting workshops and new enterprises, supporting and encouraging innovation. He was an early licenser of Evans's mill design. Invention was encouraged not only for individual financial gain, but also for the country's economic growth and entrance into world trade.

The Factory System

Industry initially took root in textile production. Samuel Slater (1768–1835) replicated British machinery to establish hydropowered yarn-spinning factories. Technology was pushing aside “homespun” fabrics created on spinning wheels and hand looms. Francis Cabot Lowell (1775–1817) and Paul Moody (1779–1831) grew the industry into all-inclusive textile mills. Raw fiber entered their factories and left as finished cloth. By 1814, powered looms were producing fabrics for clothing and bedding.

Ironworkers like David Wilkinson (1771–1852) recreated English textile machinery and evolved into mechanical engineers as they went on to develop their own inventions. The need for precisely machined, threaded parts inspired Wilkinson to create a sliding lathe to cut precision threading on metal screws, bolts, and instruments. The technology he created founded the American tool machinist industry.

Improvements in the cotton gin simplified and increased the processing of raw cotton. In the American South, slave labor subsidized production costs, making American cotton cheap. The growing availability of cotton fiber, combined with Hannah Wilkinson Slater's (1775–1812) patent for mechanically producing cotton thread (1793), ushered in cotton as a mass-produced textile. Technology made cotton a global product and transformed the American South's economy.

New technology also entered the home. Inventions like the apple parer, canned food, and the coffee percolator reduced daily work. Eli Terry's (1772–1852) mass-produced wooden clocks made desirable technology affordable for everyone.

The Challenge of Interchangeable Parts

The American iron industry was reborn in the market economy. The expertise to produce everyday ironware

had been lost over the generations of colonial ironworkers who had been pressured to supply minimally processed iron to England. In the years leading up to independence, American iron was shipped to England and forged into products and then resold to the colonists. After the war, regional foundries had to be reestablished, and skilled new immigrants reinvigorated the manufacture of iron products.

During the Revolutionary War, emergency production of cannon had occurred in small forges, but most firearms had been imported from France. In the first years of the new nation, armament manufacture became a priority. The American government's first investment in industrial research and development was to advance firearm production. Individual craftsmen producing individual guns could not deliver an adequate and reliable supply. American leaders sought to create the mass production of firearms. Achieving this technological leap required the development of precision manufacturing and interchangeable parts.

Jefferson had seen a demonstration of firearms composed of randomly selected individual pieces in France in 1785. “Interchangeable parts”—or finely produced integral pieces that could be substituted between the working elements in finished mechanical devices—became the holy grail of 19th-century manufacturing. Anyone who could successfully create interchangeable parts would forever change the production not only of guns, but all products with moveable elements—engines, clocks, sewing machines, etc.

While Eli Whitney (1765–1825) secured the first government contract to create firearms with interchangeable parts, most experts agree that he did not succeed. Thomas Blanchard (1788–1864) and John Hall (1781–1841) are the unsung heroes of American interchangeable-part technology.

In 1819 at the Springfield Armory in Massachusetts, Blanchard's workshop developed machinery with “tracer control.” A lathe cut an irregularly shaped gunstock by tracing the shape of an original item and replicating it. This innovation facilitated mass production of identical rifle stocks.

In the same year, the War Department contracted with Hall to produce 1,000 breech-loading rifles at the Harpers Ferry Armory in Virginia. By 1822, Hall and his crew successfully created interchangeable elements

between the working parts of rifles by using a “bearing point” reference. All measurements for the interworking parts were taken from this single reference point. Hall’s system assured that all of the mechanical parts could be precisely produced and uniformly fitted.

The U.S. government spent the equivalent of \$2 million on the development of interchangeable-part technology, but the investment had far-reaching consequences for American manufacturing. Blanchard’s tracer-controlled cutting enabled replication of an asymmetrical, contoured shape. The technology was used to mass-produce wooden axe handles and shoe-maker lasts. Later the concept was applied to shaping metal objects, including the common replication of keys. Hall’s method for producing precision interchangeable parts is used in every modern mass-produced automobile, airplane, electronic device, and machine—from toaster ovens to space satellites.

The Medical Sciences in Transition

Medicine was entering a period of transition. Since colonial times, most minor illnesses had been treated at home or with the aid of midwives like Martha Ballard (1735–1812). Prior to 1780, only two colonial colleges trained medical doctors: the College of Philadelphia and King’s College (which reopened after the Revolutionary War as Columbia College; now Columbia University). Harvard School of Medicine was founded in 1782, and by 1820, a growing faith in “science” placed greater confidence in college-trained male physicians.

Benjamin Rush (1745–1813), one of the foremost physicians in the young nation, personifies the transition between old methods and more science-based medicine. Rush continued the ancient practice of bleeding patients for all manner of sickness, but at the same time he led the movement to identify mental illness as a disease of the mind and not the consequence of evil spirits.

Benjamin Waterhouse’s (1754–1846) introduction of an English vaccination procedure for smallpox bolstered scientific medicine. Smallpox caused deadly epidemics in America. In 1800, Waterhouse approached President Jefferson with scientific data on smallpox immunity in people vaccinated with cowpox, a milder disease. Jefferson embraced the scientific evidence and

appointed Waterhouse to oversee a national vaccination program, the first American attempt to eliminate smallpox.

In the early 19th century, many people expected to lose their teeth by middle age. Dentist Levi Spear Parmly (1790–1859) theorized that tooth decay followed damage to the tooth’s external surface and that cleaning the teeth could prevent decay. He advanced oral hygiene by inventing dental floss.

Increased civic responsibility followed political independence and empowered citizens to improve public health. Under colonial rule, none of the large cities—Philadelphia, New York, Boston, or Baltimore—had had a municipal sewage system or public garbage collection. Sewage was dumped in the streets, and trash was piled at city outskirts. Springs, rivers, and wells, which provided drinking water, became heavily polluted. While the connection between disease and bacteria, or microbes, in drinking water was still unknown, the awful taste of city water caused concern. Civic leaders turned to inventors and new technologies to bring clean drinking water to city residents.

In 1799, Philadelphia installed the first steam-powered water pump to draw clean water from a distant reservoir into the city. Technology was now enabling cities to grow beyond local available resources.

Transportation Engineering

Construction engineering and transportation were directly impacted by independence from Britain. Prior to the war, each state had viewed itself as an insulated entity. Building was local and reflected the cultural background of the regional population. Math and engineering were not specific courses of college study. Travel was primarily by horseback, animal-drawn carriage, hand-propelled boat, or sailing ship. Road systems were minimal, and shipping lanes were often dangerous.

Mathematically talented individuals had few career paths: business accountant, ship navigator, or land surveyor. As a young seaman, Nathaniel Bowditch (1773–1838) taught himself complex mathematics to improve the safety of navigating ships along the New England coast. He created a manual that empowered even the least educated sailor to calculate a ship’s location.

First published in 1802, the *American Practical Navigator* transformed sailing safety and empowered ship crews. Captains and navigators could no longer tyrannically command crews of sailors ignorant of their location. Over 200 years after its publication, the manual continues to be revised and used around the world.

Bowditch further contributed to science in America by translating French works on theoretical mathematics and calculations on planetary movements. He provided the mathematical foundation for the study of astronomy in the United States and taught the first generation of American mathematicians.

As America entered the market economy, the need to move trade items transformed the countryside. Sailing ships had been the primary way to move goods from one colony to another, but they were limited to coastal port cities. Now, Presidents Washington and Jefferson lobbied for a national road to access the country's western interior. Where once temporary structures or ferries had crossed rivers, now individuals with vision were building sturdy bridges and planning canals.

In Europe, architects built bridges following ancient Roman arch design. Stone was the primary building material because wood was considered too precious. In America, lumber was the building material of choice; it was cheap and plentiful. Inventors like Ezekiel Reed (1772–c. 1852) and Jacob Perkins (1766–1849) were creating machinery to mass-produce nails. Self-taught construction engineers and architects experimented with novel ideas and built bridges to meet local community needs. Irish immigrant James Finley (1756–1828) patented the chain suspension bridge. Timothy Palmer (1751–1823) designed the first large-scale covered structure for the “Philadelphia Permanent Bridge.” Theodore Burr (1771–1822) developed the Burr arch truss, which supported the longest wooden expanse bridge in the world in 1804. These innovations changed bridge design and formed the foundation for modern steel-truss bridges.

Opening up the continent's interior for farming required transportation corridors through which agricultural products could be moved to ports and cities. In 1817, ground was broken on the Erie Canal. The dream was to connect New York City with the Great Lakes via the Hudson River. The Canal would stretch over 360 miles from Albany, on the Hudson River, to

the city of Buffalo, on Lake Erie, and form the largest inland canal system yet known to the world.

To raise a cargo ship 600 feet in elevation through a series of locks on a completely man-made waterway was deemed a superhuman feat. Yet, the men who achieved this engineering challenge learned on the job. James Geddes (1763–1838) and Benjamin Wright (1770–1842) were surveyors who taught themselves construction engineering. They assembled a team of individuals willing to experiment, fail, reevaluate, and succeed: Nathan Roberts (1776–1851), a farmer turned engineer, David Thomas (1776–1859), a botanist/surveyor/physician turned engineer, and Canvass White (1790–1834), the developer of a cement product that strengthened underwater.

As Americans were reshaping the countryside, the technology of their tools needed to evolve. Mechanician workshops, which had been the repairers of everyday items and builders of practical implements, became centers of machinery fabrication. Families involved with designing iron and wood fittings for mechanical devices ran regionally renowned workshops: the Jenckses and Wilkinsons of Pawtucket, Rhode Island; Simeon North's (1765–1852) metal milling shop in Connecticut, and Evans's “Mars Works” in Philadelphia. These hubs of innovation devised mechanical elements for drawbridges and canals, built industrial machinery, shaped metal for interchangeable parts, and developed engines to power the nation.

As men and animals moved boats along the Erie Canal, visionaries were experimenting with new forms of power. Robert Fulton (1765–1815) is credited with the first successful steam-powered boat, but his real contribution was marketing the technology. The steam engine evolved not from the work of one man, but from a list of competing pioneers: Wilkinson, John Fitch (1743–1798), working with immigrant mechanic Henry Voight (1738–1814); John Stevens (1749–1838); Captain Samuel Morey (1762–1843); James Rumsey (1743–1792); Thomas Paine (1737–1809); Nicholas Roosevelt (1767–1854); and Evans.

The Age of Steam

By 1814, Evans's high-pressure steam engines were powering city water systems, dredges, grain and

lumber mills, and iron and textile manufacturing, as well as watercraft. Roosevelt's steam-powered boat *New Orleans* navigated the fast-flowing Mississippi and Ohio Rivers in the newly acquired western lands. These rivers were too swift for hand-powered or sailing ships to effectively travel upstream. By 1820, 200 large steam-powered paddle-wheeled boats were opening up the Mississippi River basin to settlement, agriculture, and the establishment of large cities.

Energy for homes and even steam-powered engines would rely on wood for decades, but energy needs were changing. Initially, machine workshops and mills were located in small communities along swift-flowing rivers or streams. Hydropower was clean and renewable, but factories often discharged waste into rivers or diverted too much water, creating conflict with town residents. While hydropower remained the primary energy source until 1840, it suffered seasonal fluctuations or was disrupted completely during the winter by freezing. As cities of workers built up around industrial centers, waterpower became too contestable and unreliable.

Whale oil, used in lighting and lubricating machinery, was too costly to burn for power. To ignite the Industrial Revolution, factories needed reliable, year-round energy that could be employed away from waterways. In the coming age, corporate-funded science would transform alcohol-based fuel, anthracite coal, coal gas, and petroleum-based fuels into energy drivers.

Talented Amateurs

Pure science was difficult for practical Americans intent on building a new country to embrace. Physical sciences were only gradually integrated into America's higher education after the Revolutionary War. With the exception of Franklin, Rittenhouse, Rush, and a small number of educated physicians, most American science enthusiasts in 1780 were talented amateurs. The lack of science professionals, however, created opportunity for educated immigrants and determined underprivileged individuals.

Educated in France by one of the world's eminent chemists, Éleuthère Irénée du Pont (1771–1834) fled the French Revolution (1789–1799) and immigrated to the United States. He improved gunpowder refining

and in 1802 established one of America's first corporate chemical companies: DuPont. The War of 1812 (1812–1815) dramatically increased demand for gunpowder, and U.S. government contracts helped solidify DuPont as one of America's most profitable companies.

Freeborn African American Benjamin Banneker (1731–1806) established himself as a mathematician, surveyor, and astronomer despite little formal education. Several solar eclipses traveled across the United States between 1778 and 1806, thrusting astronomy into people's daily lives. Banneker accurately calculated the occurrence of a solar eclipse and became the first African American to publish an almanac. He used his mathematical expertise as evidence to directly challenge President Jefferson's belief that people of African heritage were intellectually inferior.

Thomas L. Jennings (1791–1859) became the first African American known to acquire a patent. Profits from his 1821 chemical dry-cleaning process enabled him to purchase his family out of slavery. Science and technology were providing new opportunities for people and changing daily life.

By 1800, the country was evolving in how it regarded the world and itself. The election of President Jefferson marked the second peaceful handover of governmental power—the union was stable. Americans could devote more time to recreational interests. As a natural history enthusiast and science aficionado, Jefferson championed the practical value of science and promoted scientific inquiry as a public passion.

Jefferson sent the Lewis and Clark Expedition (1804–1806) on the first U.S. government-financed scientific mission to map and explore the purchased Louisiana Territories. The explorers returned with natural history specimens, which enthralled the public and inspired a deeper interest in science.

In 1807, Jefferson established the U.S. Coast Survey—the country's first group of professional mathematicians and scientists. Most were students of Bowditch, and they accurately surveyed and mapped the nation's Atlantic Coast and newly acquired coastline along the Gulf of Mexico. They charted the Gulf Stream, investigated the magnetic force of the ocean, documented coastal marine life, and precisely determined longitudes using astronomical observation. The

Coast Survey remains one of America's oldest scientific institutions and in 1970 was incorporated into the newly established National Oceanic and Atmospheric Administration (NOAA).

As the country invested in science, the first generation of children born as U.S. citizens reached adulthood. The natural history movement founded by Franklin and nurtured by the APS and Peale's museum in Philadelphia encouraged public curiosity about the natural world.

Botany, biology, geology, astronomy, and natural phenomena were being taught in schools. The children of the market economy became America's first generation of science professionals: inventor Samuel Morse (1791–1872), botanist and chemist John Torrey (1796–1873), physicist Joseph Henry (1797–1878), and more.

The Fruits of Change

When Americans cast off their colonial ruler in 1781, they were forced to think, act, and provide for themselves. To meet their clothing, building, and food needs, Americans copied, improvised, innovated, and developed new technologies. By 1820, factory-produced textiles were leading the country toward the Industrial Revolution, and interchangeable-part technology was providing American manufacturing with an advantage over global competition.

Engineered roads, canals, bridges, steamboats, and public water systems were transforming the country physically and philosophically. Scientific knowledge was improving agriculture, industry, home life, medicine, construction, transportation, energy, and hopes for the future.

With the completion of the Erie Canal in 1825, Americans proved they could conquer nature and engineer projects beyond Europe's imagination. The Canal's success rippled through the American spirit. Canal engineers went on to execute more canals and roads, to design city waterworks, to plan the routes for the coming innovation—railroads—and even to influence the nation's first subway systems.

The Canal inspired the founding of the first U.S. technological research college, the Rensselaer Polytechnic Institute at Troy, New York. The Institute trained professional engineers such as Washington A.

Roebing (1837–1926), who designed the Brooklyn Bridge; Allen B. Du Mont (1901–1965), who developed television with the first practical cathode ray tube; Nancy DeLoye Fitzroy (1927–), an expert in heat transfer in space satellites; and John F. Schenck (1939–), a pioneer in magnetic resonance imaging (MRI) technology. In the 21st century, the legacy of the Erie Canal continues to educate technological visionaries.

Steam-powered shipping would evolve into steam-powered railroads. Bridge technology, developed to ford rivers, would span canyons and a continent. Technology would open up the heart of North America to mass migration.

Yet there was a dark side to America's technological growth. The engineering successes that challenged European industry and surmounted natural physical barriers bolstered the belief in "Manifest Destiny"—that Americans of Western European descent had been ordained by God to conquer the wilderness and the North American continent's native peoples. It supported the idea that one race had a God-given right to transform the land for its own purposes. Enslaving African peoples or displacing Native American cultures was deemed necessary for American advancement.

Growing populations and industrialization hungered for natural resources: agricultural land, lumber, iron, minerals, cheap cotton, abundant wheat, and new energy sources. Change was coming too fast for the social, environmental, and human costs to be fully appreciated. How would industrialization change families? How would city life affect people's relationship with nature? What impacts would technological advances have on the environment? Who would pay the consequences for unsustainable agricultural systems and unlimited harvesting of natural resources? Engineering advancements and technological innovations were driving the country forward, but not all of North America's residents would benefit, and the inequities would instigate war with Native peoples in the West and a Civil War over economics and human rights in the East.

From 1780 to 1820, America was a greenhouse for new ideas; 3,332 invention patents were registered with the U.S. Patent Office. Independence and a

diverse population created a country fertile with innovation. Most people benefited from improved daily life, health, and opportunity. Natural history was becoming a popular craze, inspiring public interest in botany and biology. Fields of scientific inquiry were growing and becoming professions. Some of the period's creative visions, however, were still dormant seeds—self-powered vehicles, controlled electricity, man-made refrigeration, and public sanitation. The technological and scientific seeds of change sown in the market economy would flourish and transform America.

Amphibious Steam Vehicle

Known as the *Oruktor Amphibolos*, the first amphibious vehicle was built in 1805 by Oliver Evans, whose visionary designs made him an important figure in the American Industrial Revolution. Although the *Oruktor Amphibolos* was technically the first automobile in the United States and the first amphibious vehicle, it was never a commercial success.

Born in Newport, Delaware, to a farming family, Evans had little formal education. He was apprenticed to a wheelwright and learned wagon making as a teenager. By age 17, he was experimenting with ways of propelling wagons and carriages without animals. Fascinated by the possibilities of the steam engine, Evans applied for exclusive rights to build steam-powered carriages in Pennsylvania. He was unable, however, to generate enough financial backing to make a go of it. By 1802, he built the first high-pressure steam engine in the United States. High-pressure engines were smaller, lighter, and more efficient. Evans's engine was portable and could be used to power a wagon. Evans realized that the high-pressure steam engine would be crucial to the development of a steam carriage.

In 1804, after receiving a patent for his steam engine, Evans approached the city of Philadelphia about the possibility of designing a machine to clean the Philadelphia docks. He had no particular interest in dredges but was anxious for an opportunity to try his steam engine. The Philadelphia Board of Health commissioned Evans to build a steam-powered dredge for the city dockyards. The Board gave Evans a substantial advance, which he used up quickly without having anything to show for it. The Board got impatient when Evans failed to produce a vehicle. He was advanced more money, and in 1805, he finally finished the machine. The *Oruktor Amphibolos*—or "Amphibious Digger"—was a 30-foot 17-ton five horsepower high-pressure steam dredge. The flat-bottomed boat had a chain of buckets to scoop up mud, and the mechanism was driven by Evans's high-pressure steam engine. The engine was a grasshopper beam engine with an iron boiler mounted on bricks. The dredge was built in his workshop one and a half miles from the

Oliver Evans invented the Amphibious Steam Vehicle, or *Oruktor Amphibolos*, in 1804 in Philadelphia. (Hulton Archive/Getty Images)

Schuylkill River, where it would be launched. To move the dredge to the waterfront and also hoping to generate some publicity for his engines, Evans mounted the dredge on four wheels and connected them to the steam engine. The first wheels collapsed under the weight of the vehicle and had to be replaced. According to Evans, he ran the machine around the city square for several days and invited spectators to donate 25 cents each. He kept half of the money for himself to fund future inventions and gave half to his workmen, who he claimed had paid for the *Oruktor's* wheels. On the day of the launch, Evans drove the *Oruktor Amphibolos* from his workshop, through the streets of Philadelphia, and all the way to the waterfront, surrounded by crowds of curious onlookers. The engine was then connected to a paddle wheel, and the *Oruktor Amphibolos* steamed down the Schuylkill River to the Philadelphia harbor. As a dredge, it was ineffective, and the Philadelphia Board of Health sold it for scrap in 1808.

Although the *Oruktor Amphibolos* itself was more of a publicity stunt than a breakthrough in

steam-powered vehicles, Evans's engines were influential in the development of steam-powered automated industrial processes. He never built another steam-powered carriage or wagon after the *Oruktor*. Because Evans tended to exaggerate his accomplishments and there are few (and conflicting) contemporaneous accounts of the *Oruktor*, some people believe that the vehicle might never have made it to the Philadelphia dockyards. An account written in 1840 claims that Evans's underwater steam engine stood rusting on the streets of Philadelphia for months. Others claim that a five-horsepower engine could not have propelled a 17-ton dredge.

HAVING traced the steam-engine from its first invention to the successful application of its power for the purpose of navigation, by Fulton, it now remains for us to continue the subject, by a brief history of its application to land-carriages on common roads, and its superior advantages on railways. Two individuals, in particular, are claimants for the honor of this invention, both of whom also claim the invention of steam-boats; but as all claims to the invention

Apple Parers

By the late 17th century, the apple was a popular fruit and a key agricultural product in the American colonies. The first apple orchard was planted in Massachusetts in 1635 by clergyman William Braxton, who had a farm in Boston's Beacon Hill. John Endicott, governor of the Massachusetts Bay Colony, planted the first nursery of apple and other fruit trees in America in 1640, while many believe that Peregrine White, the first child of the Pilgrims, planted an apple tree in Marshfield, Massachusetts, in 1648.

Apples were preserved as dried fruits and also made into applesauce, apple butter, and apple vinegar, all of which required paring and slicing, which were both difficult and time-consuming. After the harvest, early American communities held apple bees, where they socialized and pared apples. The November 1859 issue of *Harper's Weekly* reported that a popular pastime among marriageable girls during the bees was to divine the names of their future husbands by throwing the spirals of apple peel over their shoulders, looking at where the peels landed, and then trying to discern their future partners' names from the shapes of the peels on the ground. But given the drudgery of the peeling process with a handheld knife, the race was on to build an efficient mechanical tool for it.

Several individuals are credited for inventing the first apple parer. Eli Whitney, best known for inventing the cotton gin, is said to have invented one in 1778 at the age of 13. Locals in South Woodstock, Vermont, credit John Sterling for creating one in 1785. However, the official credit for the invention goes to Moses Coates of Downing's Field, Pennsylvania, who obtained the first patent for an apple parer on February 14, 1803.

The initial apple parers were handmade and primitive—they were made of wood and had a shaft with a crank on one end, and a wooden or metal fork to hold the apple in place at the other end. The crank had to be turned with one hand, with the other guiding the paring blade or knife that was mounted on a wooden handle. Types of early apple parers varied: there were straddle board, tabletop, table mount, floor pedestal, leg strap, knee hold, and bench types. As this tool evolved, the fork holding the apple was made to turn

faster by the addition of cords, belts, and gears. Yet the paring blade was still guided with the hand and was anchored to an upright post, just as in Moses Coates's invention.

Inventors during the early 19th century tried to outdo each other by creating superior versions of the parer to peel the apple as efficiently as possible. The first mechanical apple parer using a spring tension instead of the hand was created by Ephraim C. Pratt. His device left the operator with a free hand to remove the peeled apple and replace it with an unpeeled one. In his patent from October 4, 1853, Pratt claimed that his design allowed the knife to vibrate and match any irregularity in the surface of the apple or vegetable being pared. This instrument was made by Sargent & Foster's of Worcester, Massachusetts, and is considered the first cast-iron apple parer.

Subsequent inventors continued to improve this mechanical gadget. Apple parers of the late 19th century could be classified into four types based on their mechanisms: the lathe, the turntable, the arc (or geared segment), and the return (quick or otherwise).

As mass-produced food products became popular, the apple parer slowly disappeared from stores. Today, they are largely extinct, but not forgotten. They often show up at flea markets and antique shows, where collectors are willing to pay a lot to preserve a part of history with this fascinating tool.

Primary Document: Apple Parer Patent Document Image (1836)

The mechanical apple parer is a product of the Industrial Revolution in many ways. One of its less obvious connections is with the development of the Erie Canal, which allowed goods to be transported safely and affordably from the interior of the country to urban centers. With the canal, apples could be

moved in large quantities to early factories, where women used apple parers to quickly process large amounts of apples. The image below of an apple parer is from an 1836 patent document.

Babbitt, Sarah “Tabitha” (1779–1853)

Sarah “Tabitha” Babbitt was an American inventor and toolmaker, and she was a member of the Shaker community in Harvard, Massachusetts. She is credited with inventing the first circular saw used in a sawmill in 1813.

Babbitt was born in Hardwick, Massachusetts, to Seth and Elizabeth Babbitt. On August 12, 1793, she became a members of the Shakers, joining the community in Harvard. The Shakers’ name comes from their unique form of worship in which they express their joy through shaking, shouting, and dancing. Shakers practiced gender equality, adopted communal ownership of property, and emphasized simplicity in dress and architecture. They also adopted strict rules concerning celibacy, and new members came in the form of adult volunteers and the adoption of orphans.

According to Shaker history, Babbitt was working in the Harvard spinning house, watching men saw wood with a whipsaw, or pitsaw, which consisted of a narrow blade and a handle at both ends. The saw was generally operated by a two-man crew over a large pit on a sturdy platform. One person—the pit-man—would be stationed below the log, while the top-man would stand above or on top of the log. The teeth of the saw were angled and sharpened in the fashion of a ripsaw, designed to cut only on the downward stroke. Babbitt sought to rectify this inefficiency through the use of a round blade, or circular saw.

Unlike hand-operated saws, the circular saw is a power saw that uses a toothed blade to cut through materials with a constant rotary motion. The invention of this saw is commonly attributed to Samuel Miller of Southampton, England. He obtained a patent for a saw windmill in 1777. The form of the saw, though, was not well described, leading historians to believe that the circular blade was already in use and that it was the saw machine (rather than the blade itself) that Miller invented. Babbitt’s innovation was to harness the energy of water to power the circular saw in a sawmill. In 1810, she began experimenting with more efficient ways to cut lumber. Although few specific details of Babbitt’s saw have been preserved, her prototype likely consisted of a tin disk with notched edges for teeth. She mounted the disk to the spindle of her

spinning wheel, using the treadle, or foot pedal, to power the wheels and the spindle. This hand-driven model was soon extrapolated to create a larger, hydro-powered device for use in the Shakers’ sawmill.

The first recorded evidence suggesting Babbitt’s role in the invention of the circular saw appeared in a Shaker publication, the *Manifesto*, in February 1899. Although it is unlikely that she invented the device itself, Babbitt, and the Shakers, were likely among its earliest adopters and innovators.

Ballard, Martha (1735–1812)

Martha Moore Ballard played a pivotal role in her community as a midwife and healer. Through her diary, she has become a historically important female voice documenting social, economic, and religious change in rural postcolonial America.

Few women could write in the 18th century, and fewer still participated in public life, resulting in poor documentation of women’s daily lives. Because women could not own property and seldom participated in legal matters, few details regarding individual women’s lives appear in historical documents. For example, the public record of Ballard’s life is limited to her birth sometime in 1735, her 1754 marriage to Ephraim Ballard, and their children’s birth dates. Ballard was a prominent figure in her community, yet, without her journal, the only thing we would know about her life would be a family story recounted by a famous grandniece, Clara Barton (1824–1912). Barton told the humorous tale of her grandmother and

great-aunt (Ballard) hiding in a cellar to brew tea in defiance of family support of the pre-Revolutionary tea boycott. The girls claimed that the tea was for a sick neighbor. Providing medical care ran in the family; Ballard's uncle and two brothers-in-law (including Barton's grandfather) were physicians.

Ballard spent the first half of her life in the town of Oxford, Massachusetts. At the onset of the Revolutionary War in 1777, Ballard and her husband relocated their family to a frontier settlement in Maine (then still part of Massachusetts). Hallowell was a remote community of approximately 100 families spread out along the Kennebec River.

On January 1, 1785, Ballard began writing daily entries in a hand-bound journal with a quill pen and ink. She was 50 years old, and for the next 27 years, she documented her daily work providing medical care, her financial transactions and movement through the community, the textile work of her daughters, and the interactions of everyday people. Combined with maps of the area created by her husband, a surveyor, Ballard's journal weaves a history of an American frontier community.

When Ballard began her journal, she had been an active midwife for seven years. Her neighbors sought her assistance because of her skills, experience, and knowledge as the mother of nine children. Her diary documents the delivery of 816 babies, including two of her own grandchildren on the same day. While childbirth could be quite dangerous, Ballard lost very few mothers and babies in delivery, a reality that signifies her midwifery skill.

Despite depictions of Puritans as prudish, Ballard's journal reveals tolerant attitudes toward premarital sex. Over 30 percent of children in the postcolonial Northeast were born out of wedlock. An unmarried woman who became pregnant sued the alleged father for financial support. Marriage might follow, but the community's concern focused on the child's financial well-being. If the couple did not marry but financial support was supplied, neither party incurred shame.

Ballard chronicles her bachelor son being accused of paternity. As a midwife, Ballard represented the community and questioned women at the height of labor to identify the child's father. The society believed that a woman could not lie at that precise moment, and childbirth statements were legally binding.

Ballard also nursed the sick and documented the community's medical history, including physical injuries and disease. Daily entries followed the arc of a 1787 epidemic; a single sick child evolved into a community plagued by scarlet fever and fatalities. Infectious diseases swept through colonial America; Ballard herself lost three young daughters to diphtheria in 1769. Communicable diseases caused catastrophic consequences when transmitted to Native American populations.

Attitudes toward medicine were also changing. Ballard's knowledge of anatomy and physiology came from experience. Male physicians were increasingly educated from books. Initially, two male physicians worked in Hallowell. Midwives treated minor illnesses and provided primary care to women and children. Most male doctors respected the midwives' expertise, and Ballard worked cooperatively with physicians. But in the later part of her career, young doctors were attending more births and pushing midwives out of the field. Ballard believed that some doctors recklessly prescribed opiate drugs to women in labor and endangered infants with the unnecessary use of forceps during delivery.

The increasingly male-dominated medical field demeaned midwifery as unscientific, but Ballard records rare statistical evidence supporting midwifery. Ballard lost five mothers out of 998 career deliveries. In comparison, London hospitals at the time reported the deaths of between 30 and 200 women per every 1000 deliveries. Ballard also recorded fewer stillbirths and neonatal deaths than her male counterparts. Some historians believe that the trend away from traditionally trained midwives and toward male physicians, considered to be more scientifically educated, negatively impacted women's health until the mid-20th century.

Midwifery was Ballard's occupation, and she tracked payment of birth "fees" or "rewards" (Ulrich 1990, 89) in a specific column in her daily entries. She was also compensated for herbal remedies—salves, syrups, teas, and pills. As she traveled through the community, Ballard detailed her economic interactions, including barter transactions between women, which are seldom historically documented.

The early years of the United States were economically unstable. Currency was unregulated and varied between states and regions. Dollars and cents replaced

English shillings and pence, yet Ballard frequently received shillings and other foreign currency in payment.

Physical paper money or coins were frequently unavailable. Ballard was compensated for one delivery with 18 pounds of butter, a dollar in currency, and three dollars paid toward her account at a store in town. Supplies were also borrowed or purchased on account. Ballard's record of economic transactions reveals an interdependent community network.

The diary also details Ballard's daughters' economic enterprise—weaving. Ballard knitted and mended family clothing, but she was often away from home several days a week. The family grew flax, raised sheep for wool, and owned a loom. All of the Ballard women spun yarn and thread, but the girls wove textiles. Weaving had been a man's occupation, but as the process became more automated, it provided less economic opportunity. Weaving gradually became part-time work for women in the late 18th and early 19th centuries. In families, homespun garments supplemented purchased manufactured clothing or fabrics. Women in the community specialized in different aspects of textile production and traded fibers or work. Ballard bartered a pair of leather shoes for 15 skeins of yarn. Another time, she traded flax to a seamstress who sewed dresses for the Ballard women.

The textile work documented in the journal chronicles a changing economy. The development of the cotton gin by Catharine Littlefield Greene and Eli Whitney in 1793 enabled mass processing of cotton and marked cotton's emergence as an important American textile fiber. Ballard notes purchasing raw cotton for processing into fabric. Within a generation, however, this opportunity for women disappeared as industrialization made home textile production unsustainable as a trade.

The postcolonial period brought religious questioning and evolving Christian sects: Free-Will Methodists, Shakers, etc. Religious instability fragmented the Hallowell community. Ballard documented a mass murder and suicide committed by a neighbor as a tragic incident, but men in the community blamed the murderer's religious beliefs for his actions.

Disagreements over religious doctrine caused a young minister to be driven out of town. He left his wife behind, and several prominent men in town

sexually assaulted her. Initially, Ballard wrote nothing specific in her diary about the event, but her visits to the young woman reveal that she became pregnant, and Ballard was aware of the situation prior to the woman coming forward publicly. Charges were brought against the town's influential judge, who was also Ephraim Ballard's employer. Court records did not record testimonies, but Ballard wrote out her statement in her diary. The victim had confided in the midwife. Ballard had encouraged the woman to remain silent. She felt that exposing the situation would be more detrimental to the young woman.

The penalty for rape was death in this period, but few men were found guilty. Puritan society regarded men as heads of households, with women beneath them. In most circumstances, a man's testimony was considered of greater value than a woman's. The rapist was acquitted, and Ballard lost confidence in the town's male religious leaders. Interestingly, after the trial, Ballard began referring to God as the "Great Parent of the Universe," a phrasing suggestive of her shifting religious beliefs.

Martha Ballard died in 1812 in Hollowell, Maine. Her family handed her diary down through the generations until her descendant Mary Hobart donated it to the Maine State Library in 1930. There it languished until historian Laurel Thatcher Ulrich began her work with it in the 1980s. In 1991, Ulrich's book based on the diary, *A Midwife's Tale*, won a number of prizes, culminating in a Pulitzer Prize. During a period of American history documented primarily from a male perspective, Ballard's diary offers a woman's point of view. She chronicled not only daily activities but also women interacting, creating an economic network, and participating in a culture that frequently overlooked their contribution.

Banjo Clock

In 1802, Simon Willard patented and developed the banjo clock, also known as the patent timepiece. The internal movement of the banjo clock itself was designed to function as an eight-day timepiece using a pendulum 15 inches long. This meant that where most other clocks needed to be wound once a day, the banjo clock only needed to be wound once every week. Prior eight-day timepieces needed a movement of approximately six feet, by comparison, to function.

Famed clock maker Simon Willard was born in 1753 in Grafton, Massachusetts. He began studying horology (clock making) when he was 11 years old and established his first workshop in 1767. In 1780, Willard moved to Boston and set up a shop specializing in small clocks. In his lifetime, Willard manufactured over 4,000 shelf and wall clocks, including the revolutionary banjo clock and the “lighthouse clock.” The latter was the first alarm clock made in the United States.

Banjo clocks are gallery timepieces: wall-hung clocks that lack a striking mechanism, making them relatively silent. Three feet long or shorter, banjo clocks are typically characterized by having a painted dial, a long-waisted throat, and a square or rectangular pendulum box. This particular shape was responsible for the naming of the banjo clock—after the instrument it so closely resembled. The pendulum box was hinged for easy access to the weight and simplified winding.

Due to their small stature, sleek design, and mechanical improvements, banjo clocks became a staple of 19th-century life. Willard’s design became widespread and set the standard other clockmakers across the nation. This was enabled by Willard himself, as he permitted his relatives, apprentices, and associates to freely use his design. As such, many variations of the design developed. Alarm and hour-striking features were added to certain series, and grandiose versions were constructed to function at railroad stations throughout the country.

In 1801, Simon Willard was commissioned to construct a gallery clock for the U.S. Senate, which he personally constructed and installed. His time in the capitol resulted in a friendship with President Thomas Jefferson, from whom he received a silvered cane as a gift, and who later commissioned him to make one of

his patented improved timepieces for the University of Virginia. Later in life, Simon was invited to the home of former president James Madison, where he was gifted a second silvered cane in recognition of his work. Two of Simon Willard’s final works were commissioned in the capitol: the first was a meticulously designed banjo clock for the Supreme Court Chamber, and the second was a custom mechanism fitted to the statue *The Car of History*, which resided in the House of Representatives.

Blackwell, Elizabeth (1821–1910)

Elizabeth Blackwell was the first American woman to receive a medical degree. She helped establish the first medical training schools for women in the United States and England. Blackwell faced many obstacles, but in her determination, she became a trailblazing reformer.

Blackwell was born in Bristol, England, in 1821 (becoming a U.S. citizen in 1849). In 1832, the Blackwell family, which included nine children, moved to the United States. In England, her father Samuel had been a part-time preacher who spoke out against all forms of oppression. In America, he supported abolitionist and temperance causes. Samuel died in 1838, leaving the family destitute. To make a living, the Blackwell family opened a private school. However, the venture failed, and Blackwell took jobs in North Carolina and South Carolina teaching music to girls. She felt unfulfilled, though, because she wanted to make a greater difference in the world. Although her father was gone, his spirit for reform resonated with her.

In 1845, Blackwell found her calling when she visited a dying friend who explained to Blackwell that

The first woman to receive a medical degree in the United States, Elizabeth Blackwell founded the New York Infirmary for Indigent Women and Children in 1853 and later worked with Dorothea Dix to train nurses for the Union effort during the Civil War. (Hulton Archive/Getty Images)

she would have sought treatment for her uterine cancer sooner had women doctors been available to her. Due to the morality norms of society in antebellum America, many women opted to suffer with gynecological ailments in silence rather than to seek medical attention from male doctors. In keeping with these norms, male medical students were often instructed to dim the lights during childbirth and other similar procedures to keep the woman's modesty intact. These practices were detrimental to the health of women. Blackwell became convinced that women needed women doctors. While boarding with a medical doctor's family, she borrowed medical books and independently studied to prepare herself for medical school.

In a male-dominated society, her dream was certainly difficult to achieve. She applied to but was rejected by 29 medical schools on account of her sex.

Finally, in 1847, she was admitted to the Geneva University Medical School in upstate New York. Geneva was in no way more progressive than other schools; the faculty had turned the decision over to the male medical students, who had voted to admit Blackwell because they believed she would surely fail and in this way, they could teach her a lesson. Indeed, the circumstances of her admittance set the tone for her tenure at the school, where she was often ostracized and marginalized. In spite of these and other obstacles, she successfully completed her studies in 1849. However, once graduated, she found it impossible to find work as a doctor. Hospitals would not hire a female doctor. She also found it difficult to rent lodgings, because many people viewed a female doctor as an immoral or reprehensible kind of woman.

Blackwell went to Paris, where she was also denied hospital employment. Consequently, she began working in clinics for the poor, dealing with various female- and child-related health issues. In Paris, Blackwell witnessed male doctors' mistreatment of female patients, which strengthened her conviction. Unfortunately, her plan to become a surgeon vanished when she contracted an eye infection. She lost one of her eyes and ended up with diminished sight in the other. In 1858, she met Florence Nightingale, who tried unsuccessfully to convince Blackwell that nursing was the best place for women in the medical field. After more training in England, Blackwell returned to the United States right before the outbreak of the American Civil War (1861–1865).

Due to Blackwell's poor eyesight, she used her medical expertise in an administrative capacity only. During the war, she helped create the Women's Central Relief Association (WCRS) to train nurses who served as volunteers aboard hospital ships as army nurses and as relief workers. After the war, Blackwell and her sister Emily, who also became a doctor and faced similar obstacles, established the Women's Medical College—the first women's medical training school in the United States. The Blackwells' school trained more than 300 women doctors. Having eschewed marriage, Blackwell adopted a young child in 1869. The same year, she returned to England, where she remained until her death in 1910. She helped establish the London School of Medicine, the

first women’s medical school in England, where she taught gynecology.

Primary Document: Excerpts from “Address on the Medical Education of Women” by Elizabeth and Emily Blackwell (1863)

In 1863, Elizabeth Blackwell and Emily Blackwell, both medical doctors, addressed a meeting of the New York Infirmary with a speech on the importance of medical education for women. Elizabeth Blackwell faced considerable resistance to her mission both to open medical education to women and to provide medical services to poor women and children. The following is an excerpt of her address.

ADDRESS
ON THE
MEDICAL EDUCATION OF WOMEN,
PREPARED BY
DRS. E. AND E. BLACKWELL,
READ BEFORE A MEETING HELD AT THE
NEW YORK INFIRMARY,
DECEMBER 19TH, 1863.

ADDRESS

The present meeting has been called to consider the subject of organising a Medical College for Women.

I shall take it for granted, therefore, that those present approve of the study of Medicine by Women—either upon the general ground of widening their occupations—or from the feeling that in special departments of medicine, there would be an obvious advantage in being able to consult women—or that they would be valuable as teachers to diffuse sound hygienic knowledge.

There is one other point, however, on which I should like to touch—it is the question of educating good nurses. It has been frequently said to us, “If you would establish a school for nurses,—or if you would make nursing a prominent part in your medical school, it would appeal more forcibly to the public.

Now, we fully acknowledge the need that exists of a good school for nurses. The Infirmary was chartered as a practical school for nurses as well as students; and it has given similar advantages to nurses, in their department, that it has to students—viz., the opportunity of learning, by taking part in practice. In this way it has trained a succession of nurses, who are now employed in New York.

This is a matter on which we have had a good deal of experience. We were engaged in the effort made by the Woman’s Central Relief Association at the beginning of the war, to provide nurses for the first military hospitals. Several of our students also have been engaged in these hospitals. Moreover, we are well informed of the results of Miss Nightingale’s efforts, both before and since her labors in the Crimea. The result of our experience has been to strengthen our long-entertained conviction, that there must be women physicians to raise up the class of nurses the public require. It is the doctor who must train the nurse; and we have found that men, with the best intentions, find it very difficult to adapt themselves to their instruction; and moreover, that though feeling strongly the necessity, they do not take the same interest in instructing nurses that they do in teaching students. We feel, therefore, that it would be a much easier and more practicable thing to organize good instruction for nurses, after we have formed a medical school, and have drawn together intelligent women, students and assistants, than to form the school for nurses with the hope that the medical school would follow. In fact, we need the higher class to educate the lower, and without them it seems to us impossible to accomplish the work satisfactorily.

We wish it, therefore, to be distinctly understood that a radical improvement in the character and

training of nurses, in private service and in connection with public charities, will be the direct result of a superior class of educated women being engaged in medical service—that is of Women Physicians.

Let us then take up the main question, and that we may realize that the practice of medicine by women is a growing influence, and cannot be overlooked, allow me to state a few facts drawn from personal experience.

In 1845 when I resolved to become a physician, six eminent physicians, in different parts of the country were written to, for advice. They all united in dissuading me, stating, “That it was an utter impossibility for a woman to obtain a medical education; that the idea though good in itself, was eccentric and utopian, utterly impracticable!” It was only by long-continued searching through all the colleges of the country, that one was at last found willing to grant admission. When I entered college in 1847, the ladies of the town pronounced the undertaking crazy, or worse, and declared they would die rather than employ a woman as a physician. In 1852, when establishing myself in New York there was the utmost difficulty in finding a boarding-house where the simple name, as physician could be placed; ladies would not reside in a house so marked, and expressed the utmost astonishment that it should be allowed in a respectable establishment. I presented American and foreign testimonials of medical qualification, to one of the city Dispensaries, asking admission as assistant physician, in the department of diseases of women and children; the request was refused. I asked permission to visit in the female wards of one of the city hospitals; the application was laid on the table, not being considered worthy even of notice. There was a blank wall of social and professional antagonism, facing the woman physician, that formed a situation of singular and painful loneliness, leaving her without support, respect, or professional counsel.

Now these few facts taken from individual experience, are fair illustrations of the general feeling of society, and the attitude of the profession towards women physicians in 1852.

Let us see what facts present themselves to justify the assertion, that this new idea is now firmly rooted:

First,—As to the recognition of the propriety of women studying medicine. Since then ten male

medical schools have received women as students, and given them the diploma of Doctor. In three states, female medical schools have been established, holding charters granted by the State legislatures; the diploma conferred by them placing their graduates on exactly the same legal footing, as the ordinary physician; the corporators of these female colleges being respectable bodies of men and women, and in some instances enlisting the sanction, by subscription, of a very large number of influential citizens. From the most accurate data, which we have been able to collect, several hundred women have been graduated as physicians at these schools within the last ten years. At five different times, women have been admitted (as exceptions) to our large New-York hospitals to follow the visits of physicians as students, the medical faculties having given their consent in these cases. One of the largest dispensaries in the city, has during the last six years, allowed a little group of respectable female students to continue their daily attendance. The school of Pharmacy has also opened its doors to women as students. No respectable woman practitioner has now any difficulty in holding medical consultation with some of the men most skilled in the various departments of medicine.

Now all will agree that pecuniary success is a very convincing thing! We may deplore the low state of society, which will measure truth by dollars; but nevertheless we cannot shut our eyes to the fact, that the mass of mankind do judge by a low standard. To say, such and such a woman is making \$2000 a year by the practice of medicine, creates more respect for the work in the minds of most people, than any amount of argument, or abstract statement of the truth and value of the idea, would do. We can use then this poor, powerful argument of the dollar. We can point out women in Boston, New York, Philadelphia, Cleveland, and elsewhere, personally known to us who are making more than \$1000 or \$2000 a year, in a steadily increasing practice; all grown up within ten years!

Several things are proved by this fact. It shows that women can practise medicine in some fashion—they have the head to do it;—that there is nothing in the work itself, to hinder them from doing so—they have the health to do it—; it shows that women will employ them; that imperfect as their education is (as we shall presently see), and with the distinct knowledge on

the part of women, that these physicians have not the advantages of education which men enjoy, they nevertheless employ them widely and increasingly.

I think these facts will be considered as establishing the statement that the practice of medicine by women, is no longer a doubtful, but a settled thing; that a new social power is growing up in our midst, concerning which the question is—not shall it exist, but how shall it exist—shall its influence be for good or for harm? It needs but a moment's consideration to see how very deplorable the influence of an ignorant class of female physicians must be!

We believe that the time has come to form a really good school of medicine for women. The hospital organization, under the title of the N. Y. Infirmary for Women and Children, has been preparing the way for such a school for nearly ten years, and its working has been watched by the profession even more than by the community during that time. Many of the best men of the medical profession in New York are now prepared to encourage the formation of a medical school for women, in connexion with it. The Trustees of the Infirmary entered into negotiations this spring with the leading medical colleges of New York, to obtain their counsel in this matter. The subject was carefully considered by them; and the result was an expression of friendly interest in the object, with a recommendation to pursue our present plan of action.

We have thus two important elements to start with: an institution of several years' standing, whose directors, whose aims, whose manner of working are already known and approved of; and the friendly confidence of an influential portion of the profession.

Two other things are now wanted, in order to establish a college: money, which men so liberally give; social influence, which women can so effectually exert.

We need such an endowment as will enable us to secure the assistance of first-rate professors, and to commence such a system of education as I have described—thorough, and practical in its character.

It is also necessary that such a body of ladies as well as gentlemen shall join with the Trustees of the Infirmary, as corporators of the College, as will assure the public and the profession, that this effort possesses the sympathy and support of the women of New York.

In appealing to our fellow-citizens for support, or in asking the profession for their aid, it is justly a first consideration with them—is this effort endorsed by the women of our city!

The question has been asked us repeatedly by business men and by physicians.—Can you show that women want this thing done? We know that this question can be answered in the affirmative; we know that there is a wide-spread interest felt by women in this work, and we earnestly appeal to them to prove the truth of this statement by taking part in this effort.

In conclusion we ask all who feel that this is a good work that ought to be accomplished, to realize that it rests with them to assure its success, by an open and decided support.

Burr Truss Bridge

The Burr truss bridge (also called the Burr arch truss bridge) was invented in 1804 by Theodore Burr, a saw-mill owner from Torrington, Connecticut. He patented his bridge design as a special combination of an arch and a multiple-kingpost truss in 1817. The strength and stability of the bridge structure was increased by adding an arch to the kingpost truss and hence, for the first time, American bridge builders were able to build a wooden truss bridge with spans over 100 feet.

The first Burr truss bridge was built at Waterford, New York, in 1804. It was built over the Hudson River in four spans with a total length of 800 feet but was destroyed by fire in 1909. Also in New York, the longest single span (228 foot) wooden bridge over Schoharie Creek, the Blenheim Bridge, was another superb example of the Burr truss bridge. It was opened to the public in 1855 and survived until 2011, when flooding from Tropical Storm Irene washed it away. Many Burr truss bridges were built successfully in Pennsylvania, New York, and neighboring states.

A timber truss had been used for centuries for building bridges. A great Italian architect of the Renaissance period, Andrea Palladio, described the mechanism of a truss in his Treatise *I quattro libri dell'architettura* (1570). Early American bridge builders used wooden trusses for a few reasons. First, timber was abundant in the United States, and it was a lightweight and inexpensive construction material in comparison with stone and iron. Second, the unique triangular design of a truss, offering both tensile and compressive strength, provided flexibility to the bridge designers. Timber bridges were made of different types of trusses as developed by different bridge builders, such as the plank-lattice truss, the kingpost truss, the queenpost truss, etc. All of those timber bridges were covered by a roof and siding (thus also called covered bridges) to protect structural members from weather.

At that time, there were also many massive arch bridges made of stonemasonry, and hence they were labor-intensive and expensive alternatives to wooden truss bridges. However, the masonry arch bridges provided greater stability under moving loads compared to the wooden bridges, and that was the major difference between these two types of bridges. The moving load is a small part of the total load for a masonry arch bridge, since its dead load is massive. The weight in the spandrels keeps the arch from distorting under a moving load, so it does not fail by buckling. However, a moving load is the greater part of the total load for a lightweight wooden truss bridge. The arch is likely to fail by buckling when the moving load is applied only on part of the bridge.

Theodore Burr understood the load distribution mechanism better than other designers of his time and added a stiffening truss to the arch to prevent buckling. His design proved quite successful, and a great many bridges were built following his design principle. Burr himself supervised the building of five bridges crossing the Susquehanna River—four in Pennsylvania and one in Maryland—between 1811 and 1818.

The Burr truss bridge is best classified as an auxiliary arch system. The timber trusses in his design consisted of parallel chords tied together by vertical posts and stiffened by crossed braces. Each segment of the timber arch was fitted into the next by lap joints and was also attached on both sides of the posts and braces.

The segments were through-bolted to the vertical posts, sandwiching the truss. The ends of the arches were connected to the abutments below the bed timbers.

The design principle behind the Burr arch truss was that the arch should be capable of bearing the entire load on the bridge while the trusses were used to stiffen the arch for a moving load. Although the kingpost truss members were capable of carrying the load, it was difficult to calculate the load-sharing of a moving load crossing the bridge between the arch and the truss members.

Later computer models were used to analyze the load distribution of these bridges, and it was found that the truss members bore the majority of the loads while the arch provided the stability. In any case, the combination of the arch and the truss provided a more stable bridge capable of supporting greater weight than either the arch or truss alone.

Most of the Burr truss bridges were destroyed or replaced later by steel trusses. One of the refurbished Burr arch trusses is Historic Hall's Mill Bridge in Hopewell Township of Bedford, Pennsylvania. It was built in 1860, reconstructed in 1884, and refurbished over the years.

Canals

Canals are human-made channels for water. The term can be applied to those that are used for irrigation as well as for generating power, but for the most part,

canals are man-made waterways used to transport goods and people on canal boats. With waterways essentially being America's "superhighways" in the early 19th century, canals were the engineering marvels that played a vital part in the growth of the nation as well as spurring technological innovation that took America to the next level of both transportation and prosperity.

With the canal system, America's distant frontier communities could be connected with the bustling commerce of the eastern seaboard. Canal boats were inexpensive transport for west-bound immigrants and other settlers along with the manufactured goods they would need. Eastbound, canals were the conduit for raw materials such as the coal, grain, lumber, and stone that fueled the Industrial Revolution.

At their most basic level, canals are trenches filled with water. Depending on the terrain, it is sometimes necessary to line a canal with watertight material such as clay or concrete. Ideally, the canal can be filled easily with water, as in the case of those open to a river or the sea. Where the canal is not at sea level, water might be pumped or otherwise carried from nearby rivers or reservoirs.

Canals also need to be level. Cuttings and embankments can be used to correct small height differences in the terrain, but for larger deviations, other approaches such as locks must be engineered. Along the side of the canal, there must be land called a "towpath" for horses, mules, or humans to tow the boats floating down the canal. Early barges could be propelled manually by pushing a pike and using a rudder while proceeding downstream, although horses on the towpath would still be needed to haul the boats upstream. Later, barges could be motorized, though they tended to be larger and used for canals with deeper drafts. During their heyday in the 19th century, canals in America were usually about 60 feet wide and five feet deep.

Canal boats can carry many times the weight that can be hauled by a human or animals pulling a cart. Canals are not subject to rutted, obstructed, or mud-filled roads. The boats can be easily guided as they float down the canal. While a horse could carry one-eighth of a ton, a canal barge could carry 30 tons. Canals were the engineering and economic marvels of their age.

Though it is technically a "millrace" carrying water to a waterwheel and built for industrial purposes,

the oldest known canal in America was Mother Brook. Also known as Mill Brook, it ran between the neighborhoods of Dedham and Hyde Park in Boston, Massachusetts. It was constructed in 1639 to provide waterpower for mills, connecting the Charles River with the mouth of the Neponset River and the sea.

However, it was the Industrial Revolution in the 18th and 19th centuries that truly initiated the age of the modern canal system. With the coming of the Industrial Revolution, there had to be an economical and reliable way to transport large quantities of raw materials and finished goods. In 1761, the Duke of Bridgewater opened the first successful major British canal. The Duke, who owned a number of coal mines in northern England, wanted an inexpensive, reliable way to transport his coal to the industrial city of Manchester. He financed the Bridgewater Canal himself and found it to be enormously successful. The boats were horse-drawn, with a towpath alongside the canal. This system proved to be highly economical and became standard for canals both in Britain and beyond. America took note.

Lacking dukes with deep pockets, canal companies in the United States were initially chartered by individual states. Canals were seen as vital to improve inland transportation in North America, which at the time was limited to trails and coastal navigation. Canals were constructed, owned, and operated by private joint-stock companies that collected tolls for use of the waterways. By 1812, three were completed and open for business: the Santee Canal in South Carolina (opened in 1800), the Middlesex Canal in Massachusetts (1802), and Virginia's Dismal Swamp Canal (1805).

Mountain ranges often limited the inland reach of canals to a few hundred miles, with river navigation frequently blocked by rapids or waterfalls. Segments between navigable waterways involved a portage where freight was carried by horses. With more advanced engineering innovation, locks were constructed on the canals that allowed a much more efficient means of transport by raising and lowering the water level. In the early 19th century, two American canal systems emerged—one east of the Appalachians near the East Coast and one west of the Appalachians in the Midwest.

The eastern canal system connected coastal cities to sites as far inland as possible. The second, in the Great Lakes region of the Midwest, linked the Ohio River to Lake Erie, enabling access to the region's agricultural resources and carrying them back to the East Coast. Two of the most important canals were the Ohio & Erie Canal (completed in 1833) connecting Akron, Ohio, with the Cuyahoga River, and the Wabash & Erie Canal (1853) linking Toledo, Ohio, on Lake Erie to Evansville, Indiana, on the Ohio River. As the country moved westward, the 96-mile Illinois and Michigan Canal (completed in 1848) ran between Chicago and the Illinois River, becoming an important factor in the subsequent role of Chicago in becoming an important transportation hub in North America.

For several decades in the early 19th century, Ohio and Indiana built many miles of canals. However, it was two eastern canals that especially captured the nation's imagination. The Erie Canal (opened in 1825) was chartered and owned by the state of New York and financed by bonds bought by private investors. Running almost 400 miles, it connected Albany on the Hudson River to Buffalo on Lake Erie. With its numerous locks, the Erie Canal was considered the engineering marvel that opened the West to settlement. It unleashed the growth of the United States, as well as making New York City, at the mouth of the Hudson, the nation's center of finance and commerce. Soon after its 1825 opening, the Erie Canal proved commercially successful through its use of tolls, quickly paying back its investors and earning a substantial profit; construction began on an enlargement just 11 years later. Cities, towns, businesses, and industries mushroomed along the Erie Canal's route in upstate New York.

With the opening of the Erie Canal and its access to the Hudson River, there was an all-water route from the Great Lakes to the port of New York City and the Atlantic Ocean. The canal cut transportation costs in half, allowing the inexpensive transport of agricultural products grown in the Great Lakes region to the rest of the world.

The profits generated by the Erie Canal prompted a canal-building boom in the United States that peaked about 1850, when railroads began competing in price

and convenience. But in its heyday, the Erie Canal was a technological landmark. It reached into remote areas, bringing isolated people on subsistence farms in touch with the world beyond. With access to available markets, new settlers joined them by the score. The Midwest, via the Erie Canal, especially offered viable options for new immigrants (many of whom had been farm workers) beyond the teeming cities of the East Coast.

The other well-known waterway in the 19th century was the Chesapeake and Ohio Canal that linked Cumberland, Maryland, with Washington, D.C. Usually abbreviated as the C&O Canal and occasionally called the "Grand Old Ditch," it operated near the Potomac River from 1831 until its abandonment in 1924. When the C&O Canal was opened in 1850, reports noted that on its first day of business, five canal boats, loaded with a total of almost 500 tons of coal, came down from Cumberland. The C&O carried more coal on that first day than the Lehigh Canal had done for its full first year of business in 1820. Yet in 1850, the C&O Canal was already facing competition from the Baltimore and Ohio (B&O) railway. The C&O's company dropped plans to extend the canal into the Ohio Valley. But the C&O still hung on as a viable means of transport until the mid-1870s, when improved rail technology, such as air brakes and larger steam locomotives, allowed the railroad to set rates lower than could the canal, sealing the waterway's fate. In 1938, the abandoned canal was obtained by the U.S. government and is now the Chesapeake and Ohio Canal National Historic Park, a beloved recreational feature for residents of the nation's capital.

By the latter part of the 19th century the great majority of America's canals were abandoned as they lost their commercial edge to railroads. Many had limited draft, which restricted their load-bearing weight and required high upkeep, and so they were financially unable to compete with railways. Those that remain today, such as the Erie Canal and the C&O, are used for recreational purposes and are managed by state or federal governments as parks. Portions of some canals have been restored by historical groups for cultural and recreational purposes.

Ironically, the heyday of canals also led to their demise. The first small rail lines were constructed for

portage between canal segments. One of the first rail lines to be established in the United States, the Philadelphia and Columbia Railroad, was built in 1834 to complement the Schuylkill and Union canals between Harrisburg and Philadelphia, Pennsylvania. That same year, the Allegheny Portage Railroad became the first railroad constructed through the Allegheny Mountains, as it linked the Pennsylvania canal towns of Hollidaysburg and Johnstown.

Early canal enthusiasts included both Benjamin Franklin and George Washington, who believed canals were the key to America's future. For a time, they were right.

Canning Factory

Robert Ayars established the first American canning factory in New York City in 1812. The process of preserving foods within airtight containers had first been implemented by the French military in 1810, during the Napoleonic Wars. Within a year, the technology had advanced from airtight glass containers to tin cans. The factory constructed by Robert Ayars industrialized the production of tin-plated, wrought-iron cans and expanded the number of foods that could be preserved by canning.

The definition of canning itself is the preservation of perishable goods by killing microbes through pasteurization, boiling, freezing, or treatment with microbial

agents before sealing them within airtight containers. Foods preserved in this way could have dietary supplements added to their contents, including vitamins, sodium, and fiber. Canning is such an effective method of food preservation that canned goods taken off a boat that sank in 1865 were still safe to eat in 1974.

Food preservation techniques prior to canning (such as salting, smoking, and pickling) were very time-consuming and risked spoilage if the process was performed incorrectly at any intermediate stage. In addition, after the food was preserved, exposure to the elements would spoil the preserved food unless kept in an airtight container.

The sturdy design of Ayars's cans and the speed with which they could be packed resulted in a steady method of supplying sanitary and appealing food to people across the nation. Foods sold through Ayars's canning business quickly became popular with citizens throughout the eastern states and were a quick favorite of military personnel, who once regularly suffered severe starvation and food spoilage. By 1812, fruits, vegetables, meats, and oysters were all popular canned goods, particularly among the working classes. Canned foods also allowed urban populations, who did not live near sources of fresh food, to eat a variety of foods more safely. Canning factories sprang up across the nation to meet the demand, including Underwood, famous primarily for canned meat spreads.

Demand for American canned goods increased rapidly during the Civil War (1861–1865), particularly after the War Department discovered that canned food like meat was much less likely to go bad and make soldiers sick. German American Henry Heinz founded one of the nation's largest canning companies in 1869, promising consumers products that were safe and pure. Heinz got his start in canned horseradish in part because other brands used sawdust as filler.

The process of canning, both in wrought-iron tin cans and glass jars quickly became common across the entirety of the United States, as it allowed homesteads and individual families to preserve foodstuffs produced on their own lands and stave off hunger and malnutrition. By the late 19th century, companies competed in canning luxury and novelty foods. Can labels also became increasingly colorful and artistic in nature.

William Lyman invented a rotating can opener in 1870 that made opening cans significantly more convenient for consumers. In 1888, Max Ams pioneered the double-seamed tin can, a more airtight version than earlier cans.

Many ventures into the west of North America were successful due to the preserved food supplied by Robert Ayars's factory and others that had quickly risen in a rejuvenated preserved foods industry. The advancements of technology had significantly increased the distance that people could reliably travel without concern for food.

However, canning factories have historically been sites of worker abuse. Factory work is often seasonal and low wage. Factory workers, particularly immigrants, are vulnerable to unsafe conditions, low pay, and long hours. Some of the nation's most vigorous labor organization has come from these factory workers, including the United Canning, Agricultural, Packing and Allied Workers of America (UCAPAWA), which was formed in 1937 to protect food processing workers.

The cultural aftereffects of the advancements in canning are still felt today, as preservation of agricultural goods throughout the seasons has led to the expectation that most foods can be commercially purchased during any time of year, with extended freshness. It also meant that for the first time, perishable goods could be transported across the Atlantic Ocean, enabling foreign nations to consume agricultural goods from the United States, and vice versa. For many people, this was the first and most elementary form of intercultural experience—foods from a foreign land and not native to their own.

Charting the Gulf Stream

Benjamin Franklin created the most efficient way of charting the Gulf Stream in the North Atlantic Ocean with his cousin Timothy Folger and published their findings in England in 1769. Their original Franklin-Folger map of the gulf stream measures 38.5 inches by 34.5 inches and was superimposed on a map based on observations made by the famous astronomer Sir Edmond Halley, who had correctly predicted the appearance of the comet that bears his name.

Franklin made eight voyages across the Western Ocean (as the Atlantic Ocean was known at that time) between the Colonies and Europe. He observed that journeys eastward from the colonies to Europe were faster than return trips. Franklin was interested in this phenomenon as deputy postmaster of the colonies. While in England in 1768, he had heard complaints from the Colonial Board of Customs about British packet ships carrying mail that took several weeks longer to reach New York from London than average merchant ships to reach Newport, Rhode Island, from Falmouth, Cornwall.

Franklin posed the question to his cousin Timothy Folger, a Nantucket whaler and ship captain, who explained to him that merchant ships and mail packet captains traditionally tried to avoid strong eastbound mid-ocean adverse currents of up to three miles per hour. They worked with other experienced ship captains, learning enough to map the gulf stream along the North Atlantic Drift, which originates in the Gulf of Mexico, exits through the Strait of Florida, and follows the eastern coastlines of the United States and Newfoundland before crossing the Atlantic Ocean.

Franklin named the current the Gulf Stream, as it is still known today. Franklin and Folger also added notes on how to avoid the stream and adjacent shoals when traveling westward. The map was completely ignored in England when Franklin had it published by British cartographers John Mount and Thomas Page in 1770 and gave to British sailors. Perhaps the British packet captains ignored it out of arrogance and refused to admit that colonial fisherman knew more about the ocean than the superiorly trained and experienced British mariners. Perhaps they were also annoyed

because of the colonies and Franklin's opposition to the Stamp Act of 1765, which had forced the colonists to buy a British stamp for every official document they obtained.

After the commencement of the American Revolution, Franklin ceased distributing the chart to the British to prevent their fleet from having the competitive advantage of such valuable information. Subsequent versions of this map were printed in France in 1778 and in the United States in 1786. It took several decades for British sea captains to adopt Franklin's advice on navigating the current, and they were ultimately able to cut their sailing time by about two weeks. In 1853, oceanographer Matthew Fontaine Maury noted that the existence of the Gulf Stream had been known to Peter Martyr d'Anghiera and Sir Humphrey Gilbert in the 16th century, even though Franklin and Folger were the first to codify the nautical account.

In March 1775, Franklin left London and sailed for Philadelphia. The following year, in December 1776, he was sent to Paris as an envoy of the United States to negotiate a treaty with the French government. During those two transatlantic crossings, he tested the temperature of the Gulf Stream and learned that it was warmer than the surrounding waters. He incorporated these findings into the Franklin-Folger chart and had it copied and printed by Parisian cartographer Georges-Louis Le Rouge following his arrival in Paris. He provided copies of this map to all French ship captains carrying arms and supplies to the American colonies.

In 1786, after the end of Revolutionary War, Franklin published his and Folger's sketch of the Gulf Stream as part of an article in the *Proceedings of the American Philosophical Society of Philadelphia*.

The original Franklin and Folger charts disappeared and were assumed lost for almost two centuries until September 1978, when Philip L. Richardson of the Woods Hole Oceanographic Institution discovered two copies in the Bibliothèque Nationale in Paris. This finding was reported in the front pages of the *New York Times* and *Science* magazine in 1980. Since the mid-20th century, more sophisticated maps of the Gulf Stream have been charted. When the Franklin-Folger chart is compared with these charts derived from sensitive infrared photographs taken from satellites, it is

remarkable how accurately the 1769 chart depicts the path of the great river in the ocean.

Circular Saw

The circular saw is a power saw involving an abrasive disk or blade that cuts materials with a rotary motion. Its inventor is not clear. Some credit Tabitha Babbitt, an American Shaker and an inventor who was the first to affix a circular saw in a sawmill in 1813. As that story goes, she observed local timbermen sawing logs using a pit saw that had two handles and was pulled from side to side. The saw only cut the wood when it was being pulled forward; the reverse pull only served to bring it back to the starting position. Babbitt came up with a new saw designed to utilize energy the whole time that it was in motion. She created a prototype by attaching a circular blade to her spinning wheel and using the pedal to power it.

Others claim that such a saw had appeared in a different Shaker community a few years earlier. What is known is that Shakers did not patent their inventions. Instead, the circular saw was patented in the United States in 1816 by two Frenchmen who read about the saw in Shaker newspapers. Still others say that such a saw existed in Europe as early as 1777. Either way, the saw revolutionized the work of tradesmen around the world.

Coffee Percolator

The coffee percolator was invented by the renowned American-British scientist Sir Benjamin Thompson, aka Count Rumford. Thompson’s design, intended to promote sobriety, became the basis of later percolators, which remained largely unchanged in basic

A coffee percolator cycles boiling water through the grounds using gravity until the required strength is reached. The Aluminum Company of America produced this model in 1932. The electric drip coffee maker replaced percolators in the early 1970s. (Indianapolis Museum of Art/Getty Images)

design for well over a century until the widespread use of the drip coffee maker in the 1970s.

The preparation of coffee had been slowly refined for centuries. Coffee beans were roasted and ground, and then most drinkers simply poured the grounds into boiling water and poured it out once the coffee had brewed, using narrow-waisted pots to capture the grounds. Early drip pots were in use by the end of the 18th century, but the taste of the coffee was affected by the cloth filter that these pots used. An improved version of the drip pot, the first modern percolator, was invented in 1800 by the French Bishop Jean-Baptiste de Belloy. This device was further refined by Count Rumford.

Rumford, born Benjamin Thompson, was an American-born Loyalist who fled America to Britain. He was well known as a researcher, administrator, and inventor and was knighted by King George III. In 1786, with the permission of British authorities, he moved to Bavaria and assumed a series of high government positions there. He was made a nobleman and chose the name Count Rumford. One of Rumford’s obsessions was the promotion of sobriety, and to that end, he created an improved version of de Belloy’s percolator in 1810.

Modern percolators are used to heat water on a stove; the hot water rises through a small tube onto coffee grounds and then drips down into the main chamber of the percolator, to be poured out once the coffee has finished brewing. De Belloy and Rumford’s designs were much simpler, and Rumford’s design added a sleeve of insulating water. By surrounding the coffee with hot water, the coffee could be kept hot for a long period. This was an important consideration for soldiers and workmen who wanted a warm beverage without the inconvenience of a fire. In his capacity as an advisor to the Bavarian king, Rumford promoted his percolator to the Bavarian military, and it caught on quickly.

Rumford’s design spread across Europe and the United States. As coffee continued to grow in popularity, many inventors refined the percolator. In 1865, James Nason of Massachusetts patented the first modern two-chamber percolator. In 1889, Hanson Goodrich of Illinois patented a design very similar to modern stovetop percolators. While electric coffee makers have eclipsed percolators in popularity in recent decades, many consumers still use percolators

in their homes, and larger percolators remain a popular way to serve large quantities of coffee at meetings or events.

Cotton Gin

Eli Whitney's cotton gin is one of the most impactful inventions in American history. First unveiled in 1793, the cotton gin not only altered the young nation's economy, it also changed the nature of the American labor force, for in making the process of separating the cotton from the stem easier, the gin created a greater demand for slaves to pick the cotton. Given the limited market and the challenges central to effectively and profitably growing and harvesting cotton, the slave labor force in the United States had, in fact, been diminishing when Whitney created his machine. However, the increased profitability that the cotton gin inspired created an increased demand for slave labor. The end result of Whitney's invention was an increase in the importance of slavery to the American economy, an increase in its presence in the American South, and thus an increased commitment to keeping alive a practice that would ultimately be at the center of the events that led to the Civil War and which continue, in their own way, to impact daily life in the United States to this day. Yet ironically, for all its national impact, for Whitney himself, the invention was more trial than triumph, with legal battles based in disputes over patent rights costing him most of what he might have made. In frustration, he turned his creative energies to other projects, with the development of interchangeable parts being his biggest other legacy.

Whitney invented the cotton gin in the early 1790s. He first applied for a patent in October 1793 by sending a drawing of his creation to the Department of State, which administered the granting of patents. While the idea was approved, for a patent to be issued, a model had to accompany the request. Consequently, Whitney spent the next six months constructing one. Finally, on March 14, 1794, following a demonstration in the secretary of state's office in Philadelphia, Whitney was issued his patent.

The machine had had its origins in Whitney's visit to the Georgia plantation of Catharine Littlefield Greene, the widow of the Revolutionary War general Nathanael Greene. Whitney had intended to read the law and help the plantation manager, Mrs. Greene's fiancé, Phineas Miller, a fellow Yale alumnus, in whatever way he could, but upon arriving at the plantation, it took the analytical Whitney just a short time to recognize the labor problem inherent in the process of extracting fiber from cotton by hand. Indeed, the process of separating the prized cotton lint from the seed by hand was tedious and painful. One hand had to hold the seed while the other sought to tease out the useful lint. By most accounts, it took an individual 10 hours to separate one pint of cotton lint from three pounds of the harvested cotton. Ever the tinkerer, Whitney quickly set about the task of developing a machine that would make the process easier and more efficient.

The machine Whitney designed to undertake this arduous task was, in fact, a comparatively simple mechanism. Indeed, that was part of the reason that it was so easily pirated later. In Whitney's creation, the hand that held the seed was replaced with a kind of sieve of wires that were stretched out lengthwise. In his early efforts, making the proper wire was a bigger challenge than stretching it out because the ideal kind of wire did not exist. However, that problem was ultimately solved. Meanwhile, the next step was to design a means whereby the lint would be extracted. To replace the human fingers that performed the task of literally pulling out the lint, Whitney had a drum rotate past the sieve, not quite touching it. Attached to, but projecting out from, the drum's surface, were fine, hooked wires that caught at the lint. Secure behind the sieve, the seeds were restrained while the lint was pulled away. The final piece was a rotating brush that

spun four times faster than the drum, and thus it cleaned the lint off the hooks.

In an early demonstration before friends, Whitney's machine accomplished in one hour what would have been a full day's work for several workers. Not surprisingly, the gin's early demonstrations were met with an immediate and positive response. Indeed, from a business perspective, the cotton gin's popularity was its own undoing. So popular was the gin and so great was its impact that before Whitney had even completed the formal model required to obtain final patent approval, versions of the gin were already in operation on farms and plantations throughout the region. As a result, despite the patent, Whitney and Miller saw little substantive profit—certainly nothing approaching what they had hoped and rightfully anticipated. Indeed, despite a series of legal battles, the machine was pirated, copied, and used all over the South, to the distress and frustration of Whitney and Miller.

From the outset, Whitney and Miller had planned to lease their cotton gins, taking a percentage of their profits as their compensation. However, with no precedent for such arrangements, they had difficulty establishing an appropriate percentage rate, and farmers, desperate to use the revolutionary machine, were not willing to wait while Whitney and Miller worked through the business complications. Meanwhile, the two entrepreneurs, having used their resources to design and make the machine, were desperate for income and the funds needed for the ongoing struggle to establish their legal rights, a problem compounded by the fact that most of the courts in which they sought to establish their claims were in the midst of cotton country and not very sympathetic to their plight. In fact, the primary legal fight over the patents for the cotton gin was ultimately settled in 1807 after about 60 different lawsuits. But while Whitney was established as the inventor of the cotton gin and he would collect \$90,000 from the legal effort, the time and money involved in the lengthy process meant that in the end, neither he nor Miller achieved any significant financial reward.

But the business machinations surrounding the origins and early operation of the cotton gin did nothing to limit its widespread use or dampen its historic impact. Indeed, for all of the difficulties and problems

Whitney and Miller may have had, the impact of the gin on American cotton production—its amount and its method—was extraordinary. Indeed, coming at a time when new power looms in both New England and Europe could turn the cotton into cloth at previously unimagined rates, the impact of the cotton gin, both directly and indirectly, was immediately clear—and only increased.

In fact, whereas in 1791, the United States produced 2 million pounds of cotton fiber, by 1801, it had increased to 48 million; and by 1830, the country was producing half of the world's supply. That figure would rise to 1.65 billion pounds by 1860, a figure that represented two-thirds of the world's total, while also easily making cotton the nation's largest export. Quite simply, the cotton gin revolutionized cotton production in the United States, and at the same time, it changed the human dynamic involved with harvesting the crop, creating a greater demand for the labor needed to pick the newly grown cotton. In fact, the increase in cotton production was mirrored by an increase in slave labor. In 1790, the number of slaves living in the United States was just under 700,000. The number grew to a little under 900,000 in 1800 and continued to grow at an increasing pace of for each decade until, by 1860, the nation's 1.65 billion pounds of cotton was being produced on the figurative backs of just under 4 million slaves.

It is safe to say that none of this would have happened had Whitney not invented the cotton gin. Arriving on the economic scene at time when the number of slaves in the United States as well as their role in the economy were steadily diminishing, the cotton gin reversed a national trend and upended a national culture. Indeed, while there is evidence that without the new demand created by the gin, slavery might well have faded away, instead, fueled by the wave of cotton growing facilitated by the invention, development, and utilization of the cotton gin, the nation's fortunes took a very different turn—one that would ultimately result in the Civil War. In a comparatively brief period, cotton became king and the kingdom came to be maintained by a slave labor force that grew in the face of the nation's promise and at the expense of national unity.

Cotton Sewing Thread

Almy, Brown, & Slater of Pawtucket, Rhode Island, produced the first commercial cotton sewing thread in the United States under the patent of Hannah Wilkinson Slater (1775–1812), the first woman to receive a patent in her own name in the United States.

In the 21st century, cotton sewing thread is ubiquitous in our daily lives. It stitches clothing and upholstery, binds hardcover books, hems bed sheets, and is used throughout industry, including to seal large bags of dry food products. Prior to 1790, however, cotton was a rarity in America; labor-intensive processing made it expensive, and the fiber was considered too short and delicate for thread.

In the 1700s, silk, linen, and wool were the dominant thread fibers. Silk and linen were lightweight and strong but expensive; wool was abundant but bulky. In 1783, Martha Washington spent a year looking for imported cotton to spin in her plantation weave house. By the 1790s, home-based spinners were discovering cotton. Preserved quilts and textiles verify that individual women were spinning cotton fiber to use as thread.

Slater was still a teenager when she experimented with spinning a thin strand of imported Surinam cotton. To increase its strength, she and her sister spun two cotton strands together, creating a two-ply thread. While a few women may have been spinning cotton for home use, Slater envisioned mechanized production.

Born Hannah Wilkinson, her Quaker family encouraged bold problem solving. Her father, Oziel

Wilkinson (1744–1815), and brother David Wilkinson (1771–1852) were ironworkers alongside the descendants of Joseph Jencks. The Jencks’s forge established Pawtucket as a center for technological innovation. The Wilkinsons were known for casting large ship anchors, forging steel tools, and designing iron fittings for drawbridges. Slater’s brother patented his own inventions and became renowned as a mechanical tool machinist.

In 1790, Quaker investors hired Samuel Slater (1768–1835) to set up the first American hydropowered cotton mill in Pawtucket. The young immigrant stayed with the Wilkinson family and employed the mechanical skills of father and son to recreate the Arkwright carding-and-spinning machinery he had supervised in England.

The mill opened in 1791, and Hannah and Samuel were married. The young bride realized that the technology used to spin yarn and warp for cloth could be adapted to produce cotton sewing thread. She received a patent from the U.S. Patent Office in 1793. The Slater mill produced two-ply cotton thread and sold it by the “hank”—a specified length of coiled thread or yarn.

Other companies built on Slater’s idea creating four-ply and eventually six-ply cotton thread. Slater died at age 37, soon after the birth of her ninth child.

Synchronicity between the inventions of the cotton gin, cotton sewing thread, and textile manufacturing dramatically increased the demand for cotton. The American South transformed its economy to one that produced cheap cotton. Almost overnight, cotton in America went from uncommon to factory produced, never playing a large role in homespun textiles.

Dental Floss

The invention of dental floss, a cleaning aid used to remove food particles between teeth and to prevent plaque and tooth decay, is credited to Levi Spear Parmly. In 1815, New Orleans dentist Parmly, who is considered the father of oral hygiene, observed that dental caries began on the surface of the tooth's enamel. Noticing that plaque adhered to surfaces below the gumline, in the gingival area, he concluded that subsequent decay of the tooth resulted from inadequate brushing and from an incomplete removal of residual food particles. In 1819, Parmly stated that cavities could be prevented by brushing the teeth, by applying a dentifrice polisher of table salt, and by using a waxed silken thread between the teeth and around the gums to dislodge any "irritating matter" that a brush could not reach.

Techniques to remove food stuck between the teeth had been around long before Parmly, but he was the first dentist to recommend habitual brushing and flossing. In his book *A Practical Guide to the Management of the Teeth*, Parmly expressed the view that dental caries were caused by external influences related to foreign material on the teeth and that gum tissue could be improved by regular and systematic brushing and flossing. His insight predated knowledge of dental plaque and a scientific understanding of oral bacteria. Parmly described the process of how the toothbrush and floss should be used: rather delicately at first, until the gums had become accustomed to the procedure. After a few days, the gums, he stated, will respond favorably, "harden," and no longer bleed or hurt. Parmly advised his patients to use string flossing—a thin silk thread coated in wax—to clean between the teeth to prevent tooth decay.

For several reasons, however, dental floss did not achieve popularity. First, dental education was in its early stages. In the 1800s, professional dentistry was still a developing field, establishing its own identity by severing its connection with barbers and surgeons and by asserting itself as a health discipline in its own right, separate from but in concert with medicine. The first dental book published in America was Richard C. Skinner's *Treatise on the Human Teeth* (1801). The world's first dental school, the Baltimore College of

Dental Surgery, was founded in 1840 and established the doctor of dental surgery (DDS) degree. The American Dental Association was formed in 1859 when 26 dentists met in Niagara Falls, New York. Through his vision for the education of dentists, Parmly was instrumental in impacting Anglo American dental schools regarding the study, duties, practice, and qualifications of dentists.

Another reason that dental floss did not achieve immediate success involved the silk thread. Silk was expensive, and sericulture (silk culture) in America, which dates to 1603, when silkworm eggs and mulberry seeds were sent to Virginia by order of King James, was a struggling industry and never became very large or profitable. The entire silk production process was labor-intensive, requiring favorable growing conditions. Consequently, no commercial "dental floss" industries emerged.

Although historians credit Parmly with the invention of modern dental floss, he did not apply for a patent. Instead, the first patent for a dental floss device, a pocket thread carrier and cutter that is similar to contemporary dental floss packages, was granted in 1874 to Asahel M. Shurtleff. In his patent, Shurtleff mentioned silk as the best material and the least harmful agent for removing foreign matter from between the teeth. Shurtleff's company began to provide unwaxed silk floss for home use in 1882.

Shortly after World War II, Dr. Charles C. Bass, a New Orleans physician, created nylon floss as a substitute for silk floss. Through his research, he expanded upon Parmly's concepts of oral disease, demonstrating that microscopic processes cause tooth decay, and he advocated the Bass method of brushing and flossing before bedtime. Modern dental professionals routinely promote dental floss as a critical component of good dental health.

Diffraction Grating

In a multifaceted career that stamped him as one of the preeminent scientists of the 18th century, one of inventor and astronomer David Rittenhouse's most important accomplishments was his creation of the first man-made diffraction grating. That innovation, typical of a career marked by an exceptional number of path-breaking discoveries and inventions, opened the door to new opportunities for scientists in numerous areas.

The basic principle of diffraction grating were discovered by James Gregory approximately a year after Isaac Newton had conducted a series of experiments relating to light and glass prisms. Building on Newton's discovery that light was composed of a spectrum of seven distinct colors, Gregory developed the idea of a diffraction grating, which is "a band of equidistant, parallel lines, usually more than 5000 per inch (2000 per centimeter), ruled on a glass or polished metal surface for diffracting light to produce optical spectra." The diffraction grating essentially serves as a "super prism" and thus leads to an application for measuring atomic spectra in both laboratory instruments and telescopes. The diffraction grating itself consists of a large number of parallel, closely spaced slits. In its most effective usage, a diffraction grating is the preferred tool for separating the colors in incident light.

Seeking to achieve this effect, Gregory's initial work involved the use of bird feathers, which, while effectively able to separate light of different wavelengths with high resolution, lacked a needed consistency since each feather was different. Consequently, when Rittenhouse made his initial prototype in 1785, creating an instrument by stringing hairs between two fine-headed screws, he provided the desired consistency, as well as the ability to replicate experiments and work with light, that had previously been missing. At the same time, it must be acknowledged that his

early efforts were rough and rather imprecise, a reality that limited their initial usefulness. However, in demonstrating how scientists could themselves make the instrument, he not only made it possible for them to utilize the process when and how they wished, but he also provided the foundation from which future work could be pursued. Indeed, from that foundation, they could then investigate ways to improve the precision and expand the application of the diffraction grating.

Rittenhouse's creation has, according to some historians of science, proven to be one of the most valuable instruments ever developed. Indeed, its impact has included giving scientists the ability to study celestial bodies. It has also been a critical tool in scientists' work studying atomic and molecular structures. The ability to disperse light in the way it does is invaluable to a wide range of scientific exploration. In fact, diffraction gratings have many applications, being used in items ranging from spectrometers to lasers, and they also are a central component in many optical instruments. While the average person unversed in higher-level physics may not relate to the concepts that make the diffraction grating so important, it actually plays no small role in modern lives given that the basic CD and DVD media so central to entertainment today are examples of ways that diffraction grating can be used, while diffraction gratings are also used to distribute the light in products like the Nook GlowLight e-reader. Rittenhouse's invention resonates on a daily basis around the world.

Erie Canal

Built to cross New York state from the Atlantic Ocean to Lake Ontario, the Erie Canal traverses 363 miles from Albany to Buffalo. Built between 1817 and 1825, the canal was an engineering marvel of its time. Part of the New York State Canal System, this long stretch of water created a link between the waters of Lake Erie and the Hudson River, the first waterway to do so. In its time, it was the second-largest canal in the world, behind the Grand Canal in China. The creation of the Erie Canal led to an enormous growth in opportunities for the East Coast. This great North American public work established New York as the pioneer of population and transportation and as an economic powerhouse.

Rivers served as perfect waterways in the East Coast, but multiple obstacles lowered their availability as transportation. The Appalachian Mountains posed a great challenge to travel and commerce, particularly in an age when roads were poorly maintained. Goods and people had to travel overland, making the trip slow and costly.

To surpass these obstacles, prominent New Yorkers proposed the canal in 1768. The first proposal focused on improving the Mohawk River so that it was more navigable. The river, north of the Appalachian Mountains appeared promising until surveyors discovered that its level above that of seawater varied greatly. Thus, the challenge of the canal increased exponentially. For the canal to work, locks were created to

The Erie Canal at Salina St. in Syracuse, New York, ca. 1900. Canals include a series of dams and locks that create reservoirs of low-speed current flow to allow ships to traverse waterways that were once thought impassable. (Library of Congress)

balance out the different levels of land, essentially allowing boats to move up a grade.

The idea seemed preposterous to many people, both because of its size and because of the building expense. President Thomas Jefferson quickly rejected the proposal. However, DeWitt Clinton, the governor of New York, became interested in the project. Clinton became the most persistent and passionate advocate for the canal. He oversaw the first ideas of a cross-state canal and led the effort. Many people sarcastically referred to his idea as “Clinton’s Big Ditch.” He worked endlessly to gather support for the canal, garnering private funding and lobbying for public funding. On July 4, 1817, construction began.

The construction of the Erie Canal proved a difficult task, particularly as it passed through limestone and mountains. Early versions of the bulldozer were used, along with animals, to move earth and rock. The bottom and sides of the canal were lined with stone set in clay. There were no civil engineers in the United States in the early 1800s, so surveyors and engineers had to invent the engineering as they worked. The lead engineer, Benjamin Wright, and James Geddes laid out the route. Canvass White, also one of the engineers, traveled to Britain to study its canal system to help contribute to and improve the Erie’s construction. Many of the workers hired to build the canal were Irish, who were mostly recent immigrants.

When finally completed on October 26, 1825, the Erie Canal had 18 aqueducts and 83 locks. The total rise in feet from the Hudson to Lake Erie was 568. The canal was 4 feet deep, 40 feet wide, and transported boats with over 30 tons of freight. The canal boats were pulled by horses and/or mules on the towpath along the water, generally toward the north. These boats moved quite slowly, but when looking at the bigger picture, this still decreased the time and distance of travel dramatically compared to other forms of transportation at the time. It easily cut travel time in half. The Erie Canal snaked through forests, fields, mountains, and swamps. New York now had an effective way of not only transporting goods but also people. Men and women boarded boats to travel westward to visit family, find goods, and sometimes just for a relaxing journey. Immigrants began to use the

freight boats to move to new areas and start new lives. This quick and easy way of transportation helped spread the population and made New York a famous stop. New York was now an epicenter of trade for goods.

The Erie Canal also went through modifications and improvements to help keep up with its popularity. The “First Enlargement” widened the canal to 70 feet and deepened it to 7 feet. The number of locks was also reduced to 72. Now, the canal is about 12 feet deep, about 150 feet wide, and has 36 locks.

Early supporters of the Erie Canal believed it would bring the Union together by strengthening connections between the East and unsettled territories to the West. The impact of this canal dropped the cost of shipping between the Midwest and the Northeast, also lowering the prices of food and goods to and from. Tolls were collected on freight as they passed through, leading to an abundance of money due to the canal’s popularity. Total tolls collected already surpassed the construction costs after only one year of operation. This engineering success also led to economic growth, such as increases in people’s desire for education, and competition between port cities to better themselves.

The canal’s importance faded due to the increase in railroads, which provided faster and more flexible transportation of goods and people. Nonetheless, the canal still was able to handle 13 times more freight capacity than all the railroads in New York. The canal competed with railroads in the 19th century and with interstate highways in the 20th century. Yet, the canal is still the most fuel-efficient way to transport goods between the East and Midwest.

The Erie Canal gave 19th-century New York a huge commercial and technological advantage. It cut transport costs by almost 95 percent, making that city one of the most important and efficient ports in the country. The Erie Canal opened up a new highway for trade and boosted its surrounding economy. In competition, other port cities like Philadelphia and Baltimore began constructing their own canals, which led to industrial and economic advancement. The creation of the Erie Canal led to a domino effect of increased and widespread technology to improve trade.

Primary Document: Letter of Robert Fulton to George Washington Urging Him to Support the Construction of Canals (1797)

Although construction on the Erie Canal began in 1817, canal proponents had begun lobbying for it and other canals decades earlier. In 1797, Robert Fulton, primarily famous as the inventor of a steamboat, wrote the following letter to George Washington to urge him to support a canal.

HIS EXCELLENCY GEORGE WASHINGTON.
LONDON, February 4th, 1797.

SIR,—Last evening Mr. King presented me with your Letter acquainting me of the Receipt of my publication on Small Canals, which I hope you will soon have time to Peruse in a tranquil retirement from the Buisy operations of a Public Life. Therefore looking forward to that period when the whole force of your Mind will Act upon the Internal improvement of our Country, by Promoting Agriculture and Manufactures: I have little doubt but easy Conveyance, the Great agent to other improvements will have its due weight And meet your patronage.

For the mode of giving easy Communication to every part of the American States, I beg leave to draw your Particular attention to the Last Chapter on Creative Canals; and the expanded mind will trace down the time when they will penetrate into every district Carrying with them the means of facilitating Manual Labour and rendering it productive. But how to Raise a Sum in the different States has been my greatest difficulty. I first Considered them as National Works. But perhaps an Incorporated Company of Subscribers, who should be bound to apply half or a part of their profits to extension would be the best mode. As it would then be their interest to Promote the work: *And guard their emoluments.*

That such a Work would answer to Subscribers appears from such Informations as I have Collected,

Reletive to the Carriage from the neighbourhood of Lancaster, to Philadelphia. To me it appears that a Canal on the Small Scale might have been made to Lancaster for 120 thousand £ and that the carriage at 20 shillings per ton would pay 14 thousand per annum of which 7000 to Subscribers and 7000 to extension. By this means in about 10 years they would touch the Susquehanna, and the trade would then so much increase as to produce 30,000 per annum, of which 15,000 to Subscribers, the Remainder to extension; Continuing this till in about 20 years the Canal would run into Lake Erie, Yielding a produce of 100,000 per annum or 50 thousand £ to Subscribers which is 40 per cent.; hence the Inducement to subscribe to such undertakings.

Proceeding in this manner I find that In about 60 or 70 years Pensilvania would have 9360 miles of Canal equal to Bringing Water Carriage within the easy Reach of every house, nor would any house be more than 10 or 14 miles from a Canal. By this time the whole Carriage of the country would Come on Water even to Passengers—and following the present Rate of Carriage on the Lancaster Road, it appears that the tolls would amount to 4,000,000 per year. Yet no one would pay more than 21 shillings and 8d per ton whatever might be the distance Conveyed; the whole would also be *Pond Canal* on which there is an equal facility of conveyance each way. Having made this Calculation to Show that the Creative System, would be productive of Great emolument, to Subscribers, it is only further to be observed that if each State was to Commence a Creative System It would fill the whole Country, and in Less than a Century bring Water Carriage within the easy Cartage of every Acre of the American States,—conveying the Surplus Labours of one hundred Millions of Men.

Hence Seeing that by System this must be the Result, I feel anxious that the Public mind may be awakened to their true Interest: And Instead of directing Turnpike Roads towards the Interior Country or expending Large Sums in River Navigations— Which must ever be precarious and lead [no where] I could wish to See the Labour, and funds applied to Such a System As would penetrate the Interior Country And bind the Whole In the bonds of Social Intercourse.

The Importance of this Subject I hope will plead my excuse for troubeling you with So long a Letter, And in expectation of being Favoured with your thoughts on the System and mode of Carrying it into effect, I remain with the utmost

Esteem and Sincere Respect,
Your most obedient Servant
ROBT. FULTON.

Evans, Oliver (1755–1819)

A visionary inventor whose designs were often far ahead of the state of the technology of his day, Oliver Evans is best known for his invention of an automated flour mill and his development of the high-pressure steam engine. The automated flour mill was a first step toward the kind of assembly-line manufacturing that would characterize American industry in the late 19th and early 20th centuries. The high-pressure steam engine made possible smaller units that produced more power, and thus they were adaptable for ships and eventually railroad locomotives.

Evans was born on his family farm near Newport, Delaware, on April 15, 1755. When he was 17, his father apprenticed him to a wheelwright who also built wagons. Evans had no formal higher education, although he read widely in the fields of mathematics and manufacturing. One of his first inventions was a machine to make combs with wire teeth to be used in the carding process of textile manufacturing.

In 1782, Evans and two of his brothers bought some land from their father and built a flour mill. In 1784, at a facility on Red Clay Creek near Philadelphia, Pennsylvania, Evans built a completely automated mill that could turn wheat into flour with no human labor after being started. The mill was powered by a waterwheel, and none of the various subassemblies that made up the mill was a new invention, but putting them all together in a mechanical system was Evans's real achievement.

Evans patented the design (the third patent issued by the U.S. Patent Board), and while millers were

slow to embrace Miller's design, eventually license fees from this patent brought him a significant income. In 1795, Evans published a book on mill operations, *The Young Mill-Wright and Miller's Guide*, which was republished in 15 editions over the next 50 years. Many books in those days were sold to subscribers who committed in advance to buy them; the subscribers to Evans's book included George Washington, Thomas Jefferson, and Edmund Randolph, the first attorney general of the United States.

Since his youth, Evans had been fascinated with steam power. The earliest steam engines, such as those invented by James Watt in 1765, were low-pressure machines. Evans knew that machines operating on higher pressure could be smaller and yet more powerful. He believed that iron-making and machinery-making technology had advanced sufficiently to make a high-pressure steam engine a possibility.

In 1801, he built a high-pressure stationary engine for crushing stone, and in 1805, he built a steam-powered dredger called the *Oruktor Amphibolos*, or the "Amphibious Digger." It had wheels to run on land as well as water, making it the first mechanically powered land vehicle built in America. While Evans was developing the high-pressure steam engine in America, Richard Trevithick was working on the same concept in Great Britain and actually built such an engine before Evans. But historians of technology today generally credit both Trevithick and Evans with important advances in steam technology.

In 1806, Evans built the Mars Iron Works in Philadelphia and manufactured many different products there, including over 100 steam engines that were used

in a variety of applications. A fire in 1819 destroyed much of this plant, including many of Evans's unique molds and patterns. His sons eventually rebuilt the plant on a larger scale outside of Philadelphia. In his later years, Evans became involved in many patent disputes, instigating suits against millers whom he alleged were using some of his designs without license. He also became embittered by the American public's slowness to see the need for industrial advances and to accept new technology.

In 1783, Evans married Sarah Tomlinson, the daughter of a farmer from the Wilmington, Delaware, area. They had three sons and four daughters. Sarah Evans died in 1816, and two years later, Evans married

Hetty Ward, the daughter of a New York innkeeper. Evans lived the rest of his life in New York and died in New York City on April 15, 1819, just days after hearing of the fire that had destroyed his Mars Iron Works.

Primary Document: Letters from Oliver Evans to Thomas Jefferson (1804, 1808)

The following are two letters from Oliver Evans, inventor of the automated flour mill, to Thomas Jefferson regarding patent rights for his mills.

Washington Decr 24th 1804

Sir

Having heard Several members of Congress express that the President delighted much in hearing of useful Mechanical & Philosophical improvements being discovered in this country Be pleased to accept of the enclosed description which I have laid before the members of congress individually in support of my application to them for an extention of my Patent Term for my improvements on merchant Flour Mills to enable me to continue my expensive experiments in persuit of other usefull improvements which I have therin described—I am

Sir with the most profound respect your Obdt Huml Servt

Oliver Evans

Philadelphia December 9th 1808

Respected Sir

Last evening I received yours of 6th Inst enclosing 89 60/100 Dolls The sum which I suppose Captn John

Moody who is acting as my Agent in Virginia has stated to Your Excellency as due me for Licence to use my improvements in your Mills in Albemarle County For which I return you my sincere thanks Mr Moody has sent me a copy of your answer to his application Which I hope will induce others to follow your generous and Patriotic example I am sensible that the law ded not require of you or any who erected and used my improvements during the interval of my patents such payments on the grounds which I have reason to suppose has been stated by Mr Moody

I beg leave to state that I beleive Congress by the act entitled "An act for the releif of Oliver Evans" Did intend (without giving any retrospective effect) to authorise me to demand payment of all those (at least) who had my improvements in use during my patent term providing they continue to use after the Commencement of my present patent The [Provises?] Cover all from damages for what had been done purposely to remove the Idea of any retrospective effect The act securing to me the exclusive right to use, Can licence no other person

But as I have raised my price for licences from 40\$ to 100 dols under my present patent for each Mill of one water wheel and as those who erected during the term of my first patent expected licence at my old price Therefore I instruct my agents to offer to receive the Old price with interest of all such who are willing

to pay freely I Can say with truth that had all that used my improvements paid as generously as the President I might been enabled to render much greater services to my Country Boats propelled by my improved Steam Engines should have ascended the Mississippi before this day at a rate of 50 miles in 12 hours with good loads for it is a fact that they exert from five to ten times the power of the best english Engines in proportion to bulk and weight Yet I have been able in 4 years to enduce but one man to apply one to steady use. It is I beleive the best in the

world has cleared for him 20,000\$ in one year and has never went rong so as to stop the Mill one hour It is at Manehast on the Mississippi Sawing timber The working Cylinder is 9 Inches diameter 3 feet length of stroke The property of Wm donaldson of New Orleans

Sir your much Oblidged obt Huml Servt

Oliver Evans

Fire Hydrant

Frederick Graff, an engineer in Philadelphia, invented the fire hydrant in 1801. Also called fireplugs, fire hydrants provided firefighters with connections to city water sources so that trucks no longer had to carry their own water. Fire hydrants open with special wrenches and are often color coded depending upon their use.

Graff was born in Philadelphia in 1775. He started his career as a carpenter but later was employed as an assistant to B. H. Latrobe, who was in charge of developing Philadelphia's first waterworks. At that time, water pipes were made out of wood, and in the event of a fire, firefighters would dig for a pipe, make a hole in it, and use the water from the pond that formed to fill up their buckets or pumps. After the fire, the hole would be closed with a wooden cone called a "fire-plug," but the hole could be used again if there was another fire in the same area.

Graff, who was chief engineer of the Fairmount River works project, suggested the use of "ready to use" hydrants to speed water delivery and applied for a patent of his own design (1801). The hydrant was a pillar type with a wet barrel design and valve on top. The actual design, however, cannot be verified,

because Graff's patent was lost in a fire at the patent office. Graff developed an improved version of his hydrant the following year, with a valve at the bottom of the body. That same year (1802), the first order for his cast-iron fire hydrants was placed with the Foxwell & Richards Company, the large cannon maker, and Philadelphia became the first U.S. city with hydrants. Because the pipes were wooden, the hydrants had to be connected with a specially designed joint. By 1811, Philadelphia was reported to have 185 cast-iron fire hydrants and more than 200 wooden ones.

Although early fire hydrants worked well in warm months, they froze during winter. To mitigate the problem, Graff's son suggested using a wooden casting over each hydrant. Nevertheless, freezing remained a serious issue, so cities with harsh winters, like Buffalo, New York, continued to install only wooden hydrants until 1869.

The R. D. Wood Company was founded the same year that the improved F. Graff Sr. hydrant was introduced. In 1858, the company patented its own non-freezing hydrant known as the Race & Mathews hydrant, and it became the main producer of hydrants for Philadelphia after moving there in 1871.

Despite the widespread availability of fire hydrants, the ordinary pressure of the water system was ineffective in high-population-density areas with tall buildings. In 1903, Philadelphia became the first city in the world to implement a high-pressure water system capable of delivering water to the red Race & Mathews hydrants throughout the city, utilizing a system of dedicated pipes that made the hydrants operable

within two minutes of a fire signal. The total pipe length was about 56 miles and worked well until it was decommissioned in 2005.

Fire hydrants or plugs are so common in American cities today that they are nearly invisible. Though traditionally painted red, they are now color coded depending upon the class of hydrant.

Primary Document: Account of the Detroit Fire (1805)

Fire was one of the greatest threats to early American cities. The invention of fire hydrants and their installation in cities and towns fundamentally changed American history by making fires easier to fight and thus less destructive and deadly. The following is an article from the Baltimore Intelligencer about the 1805 Detroit Fire, often called the Great Fire, which nearly destroyed the city. The city had no professional fire brigades and no fire hydrants, and thus it fought the fire with volunteer "bucket brigades" that proved vastly inadequate to the task.

This event happened on the 11th of June last. The flames commenced about 9 o'clock in the morning and within four hours the whole town was laid in ashes. Only two or three buildings, of little value, situated in the borders, were preserved. About three hundred edifices, of all kinds, were consumed, among which were nearly an hundred dwelling houses, the church, several stores, the citadel, with officers' and soldiers' barracks, contractors' stores, United States store, etc. The new fort and barracks, called Fort Lernoult, a little back of the town, were not greatly endangered, and the old Block house, at the south end, escaped. In a word, all the space enclosed within picquets, and denominated the town, presents nothing but a heap of ruins, consisting of naked chimnies and cinders. The rapidity of the destruction was perhaps unprecedented, but will not appear surprising to anyone previously acquainted with the place. The buildings were mostly old, all of wood, and dry as tinder extremely crowded together on an area of about three acres—the streets very narrow (the widest not exceeding twenty feet), intersecting rectangularly at small distances—and

every square completely covered with combustibles. This mode of building the town originated, not merely for want of taste in the ancient settlers, but from the necessity of defense in war, ad this settlement has for a long time been a frontier particularly exposed to danger from the natives, and far removed from the means of external succor. It has been found necessary, till very lately, to keep the picquets enclosing the town in repair, besides being under the protection of the common of an adjoining fort and block house. The town was furnished with but one fire engine, which, with the prompt assistance of the troops formerly stationed here, has been sufficient to extinguish occasional fires upon their first appearance; but at present the troops at this station are few and want of aid from that source was severely felt on the late occasion. By what means the fire was kindled, whether by accident or design, is uncertain—there are various conjectures, but no decided opinion. It began in a stable near the United States store, on the southwest quarter, a light breeze blowing from the south. Its progress against and athwart the wind was astonishing, but in the direction of it the blaze darted with nearly the celerity of lightning, and reached the opposite extremity of the town in a very few moments. The fire in no part had diminished till the whole was in a blaze, and one immense mass of flame was presented to the eye, having the appearance of proceeding from one building of vast extent. The streets became impassable as the fire progressed, being filled from side to side with an impenetrable column of smoke and flame, which, wafted by the current of air through the north and south streets, streamed to a great distance beyond the limits of the houses. To the distant spectator, and to the wretched

inhabitants, who after a short lapse of time could be no more than spectators, the sense was at once sublime and painful, exceeding in awful grandeur perhaps almost any spectacle of the kind which has happened since the world began. It was fortunate that the catastrophe did not take place in the night, as there must have been a greater destruction of goods and effects and unquestionably of some lives. No lives were lost, but one person (a poor woman) was badly injured. Means have been taken to ascertain correctly the amount of losses in property, and progress has been made so far as to place it beyond a doubt that they exceed one hundred and thirty thousand dollars, probably reaching near one hundred and fifty thousand dollars. The conflagration took place at a time of day that the inhabitants were generally near their homes, and were enabled to save more of their moveable effects than could have been expected in so short a time as was allowed them; great quantities, however, fell a sacrifice, and individuals whose estates consisted in buildings, were in one day reduced from eligible circumstances to poverty. There is no citizen but who has suffered more or less. At present the people are scattered up and down the settlement, crowding the houses even to overflowing, occupying hovels and everything having the shape of an edifice, and several families are encamped in booths upon the public common and the highways. The sufferings of the people in the

ensuing winter must inevitably be great. We tremble to anticipate them. Hemmed in on every side by the wilderness, in some directions interminable, and in others extending too great a distance to admit of being passed by an impoverished people, they are restricted to the settlement, narrow in its extent, with indifferent cultivations, and the houses in bad repair. Not a farm is cultivated one mile from the river bank, nor a building erected. There the wilderness commences and extends to the western ocean. The settlement up and down the back of the river is but a few miles in extent, and taken up by farmers, who have no room to spare in their dwellings and raise barely a sufficiency for the supply of their own wants. The houseless sufferers have little time, and still less means, to provide new accommodations for themselves before the approach of the cold season. Provisions of every kind are at an excessively high price. Thus circumstanced, what can be before these miserable people but a winter of rigorous suffering! If credit and charity should furnish them with food, yet there cannot be shelter and covering sufficient for their comfort. Applications for relief are sent and are sending to various parts of the United States and Canada, which it is hoped and believed with not be sent in vain.

Source: "The Conflagration of Detroit." *Baltimore Intelligencer*, September 6, 1805.

Fitch, John (1743–1798)

John Fitch was an inventor and the man generally credited with inventing the steamboat. However, numerous factors have prevented him from earning the recognition that successors who built upon the basic invention have earned.

John Fitch was born on January 21, 1743, in Windsor, Connecticut, to Joseph and Sarah Shaler Fitch. Fitch received little formal education but from an early age showed an impressive mechanical aptitude. Utilizing those mechanical skills, he engaged in a wide range of endeavors, including clock making and map-making. On December 29, 1767, he married Lucy Roberts, with whom he would have a son, and soon

afterward opened a foundry in West Windsor. That venture proved unsuccessful, but a subsequent brass- and silversmithing operation flourished until destroyed by British forces during the American Revolution. Fitch served as a soldier in the Continental Army, helping secure supplies for it, including the forces at Valley Forge. Following the war, Fitch explored the West, venturing into the Ohio River Valley and recording an extensive land claim in Kentucky. Working as a surveyor in the Northwest Territory, he was held captive for brief period by some Native Americans before being released to the British forces still in the area.

Returning to Philadelphia, Fitch began to work on his idea for a boat powered by steam. His request for funding from the Continental Congress was rejected,

but a couple of state legislatures awarded him a steamboat traffic monopoly on their waters. With those grants, he constructed a new steam-powered vessel aptly named the *Perseverance*. The inaugural journey, the first successful trial of a steamboat, took place on the Delaware River on August 22, 1787, with a number of delegates to the Constitutional Convention in attendance. Although impressed, the delegates offered Fitch no financial support, although there are those who believe that the demonstration contributed to the Convention's decision to give Congress the power to "promote the Progress of Science and useful Arts, by securing for limited times to Authors and Inventors the exclusive Right to their respective Writings and Discoveries."

Fitch and Henry Voigt continued developing their vessel, and in the summer of 1790, they began offering round-trip cruises from Philadelphia to Burlington, New Jersey. On August 26, 1791, Fitch received a patent for his steamboat from the U.S. government's new Patent Commission, but the patent did not cover the full invention, and without the monopoly necessary for guaranteed financial success, many investors abandoned the project—leaving Fitch unable to continue operation even though the boat itself was a sounder vessel than previously.

Frustrated, Fitch went to France, where he had a promise of support to build a boat there. However, his arrival coincided with the French Revolution, and although he was able to escape to London, he had no business prospects there. He returned to the United States in 1794 but could find no investors. Desperate to raise funds, he went to Kentucky in 1797 to sell some land, only to discover that his claims were in doubt due to the squatters occupying it.

With his accomplishments unrewarded and unrecognized, unsuccessful in securing needed financial support, and battling depression, John Fitch took his own life on July 2, 1798.

Flatboat

A flatboat was a square-ended boat with a flat bottom commonly used for the transportation of goods and people in the 1800s. It was primarily used on inland waterways, specifically the Mississippi River and the Ohio River. The flatboat was similar in appearance to a raft, but different in that it floated *in* the water rather than *on* it. It was typically broken down for usable lumber at the end of its journey downstream. Prior to 1812, flatboats were constructed and manned by farmers who wanted to transport their crops. They were no more than 20 feet wide, to remain smaller than the river at its narrowest point. The flatboats varied in length, however, with the smallest being 20 feet long and the largest 100 feet long. The boats were no longer than this so that the farmers could still navigate properly. The largest of all the flatboats were called things like "Mississippi broadhorn," "New Orleans boat," "barge," and "ark," for a few of the more common nicknames. In the early days of flatboats, these larger boats were susceptible to attack by Native Americans. They were therefore built like fortresses, with only one door and very small windows; they were covered along their entire length to keep their cargo safer.

Flatboats could carry variety of goods. Most commonly, agricultural goods like corn, potatoes, wheat, and whiskey were carried downstream from agricultural areas to urban areas. The boats could also accommodate livestock such as chickens, cows, and pigs. Shopkeepers used them as additional storage areas, ministers used them as chapels, and financially disadvantaged families used them as housing. They were even used as floating brothels, slyly called "gunboats." Although the type of goods transported varied, flatboats were a necessity in 19th-century America.

Jacob Yoder, a farmer, built the first flatboat to ship flour from Brownsville to New Orleans via the

A flatboat loaded with men and a cargo of animals floats down the Ohio River. Pennsylvania farmer Jacob Yoder invented the flatboat in 1781 to ship flour down the Mississippi River to the port of New Orleans. (Library of Congress)

Mississippi River. Before the War of 1812, flatboats were the preferred method of transporting goods downstream. Building and using a flatboat in the late 1700s and early 1800s took serious consideration by the farmer. Materials to build one cost about \$75 in 1800 (equivalent to over \$1,000 in 2015), but it required minimal tools and training to manufacture. The boats were especially appealing to farmers in the northern regions of the United States, who would have had no other way to export their goods to market if not for the accessible transportation that the flatboat offered.

Depending on size, some flatboats required as many as four crewmembers and a pilot. It took anywhere from a month to a month and a half to complete a journey downriver. Although the journey downstream was relatively easy, the return home was generally considerably more difficult. Because the flatboats were disassembled upon arrival at their final destination,

farmers and merchants had no easy passage back to their home bases. Passage via keelboat or hired coach was expensive. Railroads offered an affordable return passage, but rail lines didn't always go where people needed to go. People who preferred to walk spent up to three months in their travel home.

Although flatboats had their disadvantages, the benefits outweighed the cost for many Americans. For the money the farmers spent on building and the inconvenience of return travel, they could make about \$3,000 selling their crops downriver and about \$16 back on the lumber from the disassembled boat.

Flatboats also increased the amount of "exotic" trade between the northern and southern United States. Parrots and bananas returned to the North with the farmers along with tales of far-off lands in the South. Even Abraham Lincoln, the 16th president of the United States, piloted a flatboat in 1828 and again in 1831. It was during Lincoln's travels that he saw

slavery in the South firsthand, including a slave auction in New Orleans.

Since the biggest disadvantage to flatboat travel was the tedious return journey, the process to find a more convenient possibility was expedited. Many people viewed the introduction of the steamboat as the option for which people had been waiting. The popularity of the steamboat began rising in the early 1810s because of its benefits to farmers trying to return home after boating downstream. This changed the return time from months to just days. The ease of travel also cut flatboat labor costs by a large margin while maximizing profit on goods. Steamboats often also towed flatboats filled with goods upriver, which further increased farmers' incomes.

The popularity of steamboats caused over a six-fold increase in the amount of flatboat journeys and truly made the industry boom. The onset of the steamboat also changed the flatboat crews—what once was a side job for farmers had now become a skilled profession. People could make a career out of piloting a flatboat since the return journey time had so drastically decreased. This switch from “dealer boatman” to “agent boatman” greatly reduced the amount of lost cargo as well as the number of boat crashes. Poor construction and rotted wood led to many wrecks during the early flatboat era. There were no dams in place to deepen the river, so the water was meandering and shallow. The boats themselves were difficult to steer, and the “dealer boatman” (mostly farmers) often had no previous experience navigating watercraft of that size downriver. Eventually, railroads were used to take farmers back upriver after their journeys downstream. Although this expedited the process even further, the increased popularity of railroads and steamboats eventually overtook flatboats as a predominant form of transportation.

Fulton, Robert (1765–1815)

Robert Fulton was a late 18th- and early 19th-century artist-turned-inventor and businessman. While he is best known in conjunction with his development of the first commercially viable steamboat in the early 19th century, a development that changed the face of American travel and commerce, he was also a central figure in the invention of a number of other important devices in the early 1800s.

Robert Fulton was born in Little Britain in Lancaster County, Pennsylvania, on November 14, 1765, one of five children born to Robert and Mary Fulton. His father was a farmer, but he lost the family farm in 1771, which forced the family to relocate. They were living in Lancaster, Pennsylvania, when Robert Fulton Sr. died in 1774.

Robert was given his early education at home before attending a Quaker school. He initially worked at a jewelry shop in Philadelphia, where he became skilled at doing miniature portraits on ivory for lockets and rings. Seeking to further his artistic efforts while demonstrating a lifelong talent for making acquaintances of those who could further his career, Fulton met and painted a portrait of Benjamin Franklin, who provided introductions to other local luminaries who sat for the young artist.

In 1787, Fulton traveled to London, where, with the help of the painter Benjamin West, he was able to secure a number of commissions for both portraits and landscapes. While he achieved modest success, with a sampling of his work being exhibited in London's Royal Gallery, Fulton realized that his future was not in painting. Instead, he turned his focus to canal engineering, a subject in which he had become interested during his European travels. He furthered his interest and established his expertise with the publication in 1796 of *Treatise on the Improvement of Canal Navigation*, a work dealing with a comprehensive system of inland waterways.

In addition, based on his fascination with canals and steam-powered boats, the one-time artist started to design his own ships, with the dream initially of selling his creations to the British Navy. His early efforts were wide-ranging and included the development of a

torpedo as well as various aquatic vessels. Indeed, in 1797, Fulton, having developed a plan for a submarine, went to Paris and proposed to the French government that his creation be used against the British in their ongoing war. The French rejected his proposal, but in 1801, after building the *Nautilus* at his own expense, it was used against the British in an effort to sink their blockade. It proved unsuccessful. In 1804, he went to Britain, where he helped develop the first advanced-design torpedoes for the Royal Navy's forces.

Fulton returned to the United States in 1806 and, partnering with influential New York politician and one-time ambassador to France Robert Livingston, he began work on what would become the *Clermont*. Indeed, Fulton's genius came not, as is often reported, in the invention of the steamboat but rather in the development of the first commercially feasible one.

Indeed, John Fitch had developed the first successful steam powered boat in 1787. After a patent battle, Fitch shared the patent with James Rumsey and John Stevens. Failing to attain a monopoly, he lost investors and never capitalized on his invention. This created an opportunity for Robert Fulton to design and manufacture a sturdy, affordable steam-powered boat.

Fulton's steamboat, the *North River Steamboat*, later renamed the *Clermont*, had sleeping accommodation for lengthy trips and a separate lounge for women. The boat made its first trip up the Hudson River from New York City to Albany in August 1807. The ship was 142 feet long and 18 feet wide and had an average speed of 4.7 miles per hour. The ship was rebuilt during the winter of 1807 to 1808 to make her six feet wider, an improvement that stabilized the ship. The rebuilt ship also featured improved steering and rudder systems. Most important, unlike previous steamboats, the *Clermont* proved profitable.

In September 1807, Fulton and Livingston had established the North River Steamboat Company. Operating on the Hudson River between New York City and Albany, the company offered a 32-hour round-trip travel option. Before his death in 1815, Fulton had directed the construction of 17 steamboats, with another 6 of his design being constructed by other companies. By 1840, there were over a hundred steamboats on the Hudson River alone. More traveled the

Ohio River, Mississippi River, the Atlantic Ocean, and other major waterways. The 19th century was, among other things, the era of the steamboat.

With his business prospering and boats operating on rivers beyond the Hudson, Fulton pursued other interests. Befitting his longtime interest in canals, in 1811, Fulton became a member of the Erie Canal Commission. Fulton married Robert Livingston's niece, Harriet Livingston, in 1806. The couple had four children. On February 24, 1815, Robert Fulton died from pneumonia that he had developed after venturing into icy water, trying to rescue a friend from the frozen Hudson River.

Fulton remains among the most famous of American inventors. Numerous towns and counties are named after him, and there is a statue of him in the U.S. Capitol's Hall of Statues. Five U.S. Navy ships have been named USS *Fulton*, and in 2006, he was inducted into the National Inventors Hall of Fame.

Gas Tungsten Arc Welding

Gas tungsten arc welding (GTAW) is a process in which an arc of electricity is created between a tungsten electrode and a piece of metal that needs to be welded. It is used on almost every metal with or without filler metal. Welded joints obtained by GTAW are very high quality and are commonly used in critical environments like nuclear and aeronautic ones. Alternative current is also used in welding for alloys that have oxide surface layers like aluminum, copper, and magnesium.

The discovery of gas tungsten welding started with short electric arc in 1800 by Humphry Davy and then in 1802 with continuous electric arc by Vasily Petrov. GTW was slowly developed because it wasn't until 1890 that C. L. Coffin had the idea of welding in an inert gas atmosphere. From the beginning, welding materials like magnesium and aluminum was difficult because of the way the metals responded to the air and resulted in porous, dross-filled welds. A solution used in the 1930s was to employ bottled inert gases; a couple of years later, the aircraft industry started to use a direct current and gas-shielded welding to weld magnesium. It wasn't until 1941 that the process was perfected thanks to Russell Meredith of Northrop Aircraft, who named the process "Heliarc." But the official term used by the American Welding Society is "gas tungsten arc welding." A chemical company helped improve the process by using a wide range of air-cooled and water-cooled torches and gas lenses, but it still had a problem because of the overheating electrode. They tried to fix this by changing the electrode from positive to negative, but that made it incompatible for welding many nonferrous materials.

Through research, it was found that alternating currents helped create high-quality magnesium and aluminum welds. Once the process became popular in the 1950s, the quality of aluminum and magnesium welding was lowered, so nowadays, it is rarely used with GTAW. The tungsten inert gas (TIG) process was fouled with the use of shielding gas that had an oxygen compound; like carbon dioxide, it ends up contaminating the tungsten electrode. In 1953, a new process called plasma arc welding was based on the development of GTAW, leading to greater control and improved weld quality by using a nozzle to focus the electric arc. However, plasma arc welding is limited to automated systems, and GTAW is a manual, handheld method.

Development within the GTAW process has continued, and today, many variations exist. Among the most popular are the pulsed-current, manual-programmed, and increased-penetration GTAW methods.

Greene, Catharine Littlefield (1755–1814)

The widow of Revolutionary War hero Nathanael Greene, Catharine Littlefield Greene, was also probably a coinventor of the cotton gin. Catharine Littlefield Greene, known as "Caty" to her friends, demonstrated strength as a military wife, acumen as a businesswoman, and creativity as a contributor to the invention of the cotton gin. She is notable as an early American woman active in science and innovation.

Born in Block Island, Rhode Island, on February 17, 1755, Greene was daughter to Phebe Ray, a descendant of the island's founders, and John Littlefield, a Rhode Island legislator. When she was 10, her mother died and she entered the care of relatives in East Greenwich, Rhode Island. The aunt and uncle charged with Greene's care were socially and politically prominent. Her uncle, William Greene, later assumed the governorship of Rhode Island.

In 1772, Catharine Littlefield Greene met Nathanael Greene, a merchant and distant relation of her uncle. The two married in Greenwich, Rhode Island, on July 20, 1774. They made their first home in Coventry, Rhode Island. Together, they raised five children: George (b. 1776), Martha (b. 1777), Cornelia Lott (b. 1779), Nathanael Ray (b. 1780), Louisa (b. 1783). A sixth child, Catherine (b. 1785), died as an infant.

When the American Revolution began, Nathanael Greene became Rhode Island's brigadier general. Despite others' objections, Catharine Greene visited her husband in battle. When possible, she was accompanied in these travels by the couple's young children. The soldiers respected her fortitude in spending time at war-time encampments. Nathanael Greene went on to serve with the Continental Army and to command Washington's southern forces, attaining the rank of general.

After the war, Catharine and Nathanael Greene relocated to Georgia to develop land he had received in recognition of his military leadership. The property, located in the vicinity of Savannah and known as Mulberry Grove, became the family's new home. Following Nathanael Greene's death in 1786, a tutor charged with educating the Greene children stepped forward to assume additional duties, assisting Greene in managing the plantation.

At Mulberry Grove, Catharine Greene received notable visitors, including George Washington in 1791. Greene had sought for years to free her husband's estate from debts incurred during the Revolutionary War: out of urgency, Nathanael Greene had personally guaranteed the costs of acquiring sufficient clothing for his troops during a South Carolina campaign. By 1792, Washington forgave the sizable debt that had plagued the family's postwar finances.

Later that year, when Eli Whitney arrived to tutor her neighbor's children, Greene persuaded him to modify his plans. She invited the recent Yale graduate to live at Mulberry Grove and to serve as a handyman and mechanic. She also gave Whitney space for a makeshift laboratory for his scientific and mechanical experiments. During his stay at Mulberry Grove, Whitney learned from Greene about the challenges of deseeding the cotton crop. In a year's time, the two shared conversations that resulted in the design and redesign of the cotton gin.

Questions surround the origin of this invention. While accounts vary, some historians contend that it was Greene who devised the cotton gin. Others suggest that the innovation was the result of collaboration in which Greene suggested the concept and revised the original design. Other people believe that Greene underwrote the costs of the prototype and its patent. In this era, women were not permitted to hold patents, so Whitney could not have put her name on the patent even if he had wanted to.

Catharine Greene's eldest son, George, died of accidental drowning in 1793. Initially, the 18-year-old was buried on the premises at Dungeness. In 1901, George Washington Greene's remains were relocated and interred with his father's at a Savannah monument to the Revolutionary War hero.

In 1796, Catharine Littlefield Greene married Phineas Miller, the tutor who had assumed management

of Mulberry Grove. Martha and George Washington served as witnesses to the marriage. When the family sold the property two years later, they relocated to Cumberland Island, Georgia, where they presided over another plantation, Dungeness. Greene remained there following Miller's death in 1803. She died in 1814 and was buried at Dungeness.

High-Pressure Steam Engine

The development of the high-pressure steam engine in the years between 1801 and 1806 established Oliver Evans as one of the most influential and prolific inventors in the early United States. Although credited with approximately 80 inventions, the high-pressure steam engine was Evans's most important. The engine was also the source of his deepest disappointment, as he was unable to develop and utilize the engine to the degree he believed possible.

With numerous other inventions already to his credit, including an automatic flour mill, Evans moved to Philadelphia around 1790 and turned his attention to investigating the idea of high-pressure steam power. He believed that the application of high-pressure steam to a piston would increase its effectiveness and utility, allowing for a smaller engine to do a job previously done only by a large one. In his view, the reduction in size would allow the engine to be used more broadly, even perhaps as a power source for wagons. With his dream, he foretold the "horseless carriage," or automobile.

In 1786, Evans asked the Pennsylvania legislature for an exclusive grant to build steam engines for use over the public roads. Unconvinced of the value of his idea, the legislature denied his initial request. However, in a subsequent session, it granted him the right to design a steam-propelled carriage. An inability to secure the necessary funding brought the project to a halt.

Reflective of his belief that the engine could be broadly adapted, in 1803, Evans shifted gears, unveiling a steam-powered engine that was capable of driving 12 saws through a hundred feet of marble in 12 hours. In addition, adding to its utility, the machine was portable. In 1805, under a patent originally granted in 1789, Evans created an amphibious steam-powered wagon. It was built on a commission he had gotten from the Philadelphia Board of Health. The machine, named the *Oruktor Amphibolos*, translating to “Amphibious Digger,” was a 17-ton high-pressure steam-powered dredge, whose purpose was both to deepen the Delaware River dock area as well as to clear out the muck that collected around the city’s dockyards. It was this work that finally proved the machine’s usefulness and hinted at the true potential of high-pressure steam engines. Further evidence came when a similar engine was able to power a wagon so as to transport 100 barrels of flour from Lancaster to Philadelphia in two days, a marked improvement over the three-day journey required of a normal horse-drawn transport.

In 1807, Evans founded the Mars Iron Works in Philadelphia as well as an additional factory in Pittsburgh in 1811. Both facilities were designed to build customized steam engines as well as boilers for steamboats, factories, and mills. Believing deeply in the potential of steam-powered engines and buoyed by his initial successes, Evans continued to refine the steam engine, ignoring critics who charged that it was dangerous and impractical. Indeed, as he had done to get attention for an earlier invention, the grist mill, he wrote a book, *The Young Steam Engineer’s Guide*, to help educate people. He also lobbied Congress for recognition and support.

A true visionary, Evans would not live to see his engine become a central factor in American life. Yet he anticipated what was to come. In 1812, he predicted

people driving down roads much faster than horses could take them and flying through the air with the birds: “The passengers will breakfast in Baltimore, dine in Philadelphia, and sup at New York the same day.”

Evans’s first wife, Sarah, died in 1816. He remarried to Hetty Ward in 1818. In April 1819, he learned that his Mars Iron Works had burned down. He died in New York City four days later and was buried in New York City.

Interchangeable Parts

Interchangeable parts are parts that are manufactured to be identical and thus interchangeable with others of their type. The introduction of identical parts revolutionized goods assembly, making it easier to produce large numbers of one type of product on an assembly line using unskilled laborers.

Cotton gin inventor Eli Whitney played an instrumental role in the development and implementation of the concepts of interchangeable and sequential parts, a concept that was critical to the development of mass production as well as serving as the forerunner of the assembly line that would ultimately play such an important role in revolutionizing American industry. Modern historians now view the development of the concept as a product of a number of inventors and creative individuals, including Whitney, all working around the same time with the sometimes disparate areas of their work all ultimately coming together in the development of this all-important process.

Ironically, Whitney's involvement with sequential and interchangeable parts resulted, at least in part, from frustration with his efforts to make his invention of the cotton gin profitable. With almost no profit yet realized, litigation continuing, and bankruptcy looming, in 1798, Whitney secured a contract from the U.S. government to produce 10,000 guns in anticipation of a war with France. The contract, calling for the guns to be delivered in 1800, was negotiated through fellow Connecticut native and treasury secretary Oliver Wolcott Jr., and was more a testament to his skills as a businessman and a salesman than as a gun manufacturer. Indeed, while the cotton gin had cemented his reputation as an inventor and the contract was the beginning of a robust arms business, at that point in time, Eli Whitney had no experience making guns and no real sense of how a musket was made.

But, as he had in developing the cotton gin, Whitney quickly assessed the challenge and developed a solution. Working in the New Haven, Connecticut, factory originally built to manufacture cotton gins, Whitney realized that the musket "was a complicated engine and difficult to make." Believing that the difficulty stemmed, at least in part, from the lack of consistency in its individual parts, Whitney set out to address that central concern. In typical fashion, he tinkered until, in 1798, he determined the best way to build a rifle. With that concept in hand, he designed a template for each individual piece. This allowed him to make multiple numbers of each piece, which in theory could then be assembled at will since each barrel, each stock, etc. was the same. The idea represented a major breakthrough and held great promise for future manufacturing, but it was not original to Whitney. Rather, while its origins are unclear, there is ample evidence that it was being pursued by other Americans as well as in Europe.

For all of Whitney's advances, he was unable to deliver the contracted number of rifles on time, and with Congress questioning his efforts, the creative Whitney staged a demonstration aimed at keeping his congressional benefactors at bay. While the demonstration's validity was later discredited, Whitney was reported to have assembled a number of guns from unorganized piles of unmarked parts, all lying out in

front of the congressional observers. Impressed with the demonstration, however staged it may have been, Congress subsequently issued a set of standards for U.S. equipment while also giving Whitney more time to fulfill his contract. It would ultimately take eight years for him to do so, and he would again have to respond to congressional doubters, who this time also questioned his costs. However, in another innovation, Whitney defended himself by essentially introducing the concept of cost accounting, adding another credit to his list of contributions to the developing industrial process. That, plus the quality of his guns, not only allayed the government's fears but earned him a contract for an additional 15,000, an order that was filled within four years.

In the end, the development of interchangeable parts represented a major step in the nation's industrial growth, with more products able to be produced faster, a development that allowed for greater production speed and lower costs. It also served as the foundation for the subsequent development of the assembly line. In the end, while Whitney likely did not wholly deserve all the accolades that came his way, his work was central to ushering in the American machine age.

Internal Combustion Engine

The internal combustion engine (ICE) is a type of heat engine that generates power by burning fuel (such as petroleum or natural gas) with an oxidizer (such as air) inside a combustion chamber. The high-pressure gases produced by this process are typically applied to pistons, turbine blades, nozzles, or other mechanical parts to create desirable motion. In this process, chemical energy is transformed to mechanical energy. There are many variant of ICEs, such as two-stroke, four-stroke, or six-stroke piston engines, Wankel rotary

The four-stroke engine cycle begins when an explodable mixture of gas and air is drawn into the cylinder by the piston (induction stroke), compressed (compression stroke), and ignited (combustion stroke). (Science & Society Picture Library/Getty Images)

engines, gas turbines, jet engines, rocket engines, etc. Different type of ICEs are used in automobiles, motorcycles, ships, airplanes, rockets, and other machinery.

The first commercially successful ICE was built in 1859 by Jean J. Lenoir, a Belgian engineer; he used it in his automobile as well as in his boat. The modern ICE was first developed in 1876 by a German engineer, Nikolaus A. Otto. Many modern automobiles use four-stroke Otto cycle engines that originated from his design. In this type of engine, the piston completes four separate strokes or cycles while turning a crankshaft. These are as follows:

- 1) *Intake stroke*: In this downward stroke, the intake valve opens up, and the piston pulls an air-fuel mixture into the cylinder.
- 2) *Compression stroke*: In this upward stroke, the air-fuel mixture is compressed in preparation for ignition. Both intake and exhaust valves are closed at this point.
- 3) *Combustion or power stroke*: The highly pressurized air-fuel mixture is ignited by the spark plug (in a gasoline engine) and creates a small-scale explosion. The explosion forces the piston to move downward, which in turn rotates the crankshaft and ultimately the tires. Thus, chemical energy transforms to mechanical energy in this phase.
- 4) *Exhaust stroke*: In this upward stroke, the exhaust valve opens to release the burnt gases.

These four cycles repeat continuously to facilitate the movement of the vehicle.

Early ICEs were started by hand-cranking. However, all modern small- and medium-size ICEs use electric starters, while pneumatic starters are used for large engines.

The first commercially successful two-stroke, or two-cycle, engine was patented by Dugald Clerk in England in 1881. As the name indicates, this type of engine completes the power cycle in two strokes—*upward* and *downward*. The end of the combustion stroke and the beginning of the compression stroke take place simultaneously, while the intake and exhaust function occur at the same time. Two-stroke engines are much lighter, since they have fewer moving parts compared to four-stroke engines. The gasoline-fueled two-stroke engines have been popular for motorcycles and small engine devices such as chain saws. However, the diesel version of the two-stroke engine is also used in large operations such as marine propulsion, railway locomotives, and electricity generation. A two-stroke engine can be more efficient than a four-stroke engine, since heat transfer from the engine to the cooling system is less for the former type.

The emissions from burning gasoline contain carbon dioxide (CO₂), a greenhouse gas (GHG) that causes global warming. Many approaches are being pursued to reduce engine emissions. For example, the Environmental Protection Agency (EPA) in the United States outlined the fuel economy standard for new cars and trucks for the model years 2012 to 2025: a gradual increase to 45 miles per gallon (mpg) for average cars and 32 mpg for average trucks by 2025. This restriction will motivate companies to improve the efficiency of ICEs.

Research continues on how to improve the efficiency of both gasoline- and diesel-powered vehicles. Other renewable fuel sources, such as bioethanol, methanol, and biodiesel are also being considered to make ICEs more sustainable. Auto companies can achieve higher fuel economy and lower GHG emission, along with a reasonable price tag, in hybrid vehicles that are equipped with ICE and electric motors (e.g., the Toyota Prius). New technologies such as smaller engines with turbochargers, direct fuel injection, variable valve timing, and others are being investigated to produce more power, substantial fuel

economy, and lower GHG emissions. For example, Ford's Eco-Boost uses a combination of turbocharging and direct fuel injection to improve fuel economy without sacrificing the engine's power. Other companies such as BMW, Mercedes, Toyota, and Volkswagen are also using similar strategies in their newer models.

Jefferson, Thomas (1743–1826)

Although he is primarily known for having served as the third president of the United States of America and as the author of the American Declaration of Independence, Thomas Jefferson (1743–1826) was also a prolific inventor, with a number of original inventions and improved versions of already-existing objects to his credit including the pantograph, a revolving chair, a wheel cipher, a sundial, a pasta machine, a mold-board plow, a sundial, the Great Clock at Monticello, a revolving book stand, automatic double doors, a lap desk, the pedometer, and more. However, he never applied for a patent in his own name. This was grounded in his belief that inventions should be as widely available as possible so as to benefit all of society instead of solely making money for their creators.

Given that Jefferson was a prolific writer of letters (it is estimated that he wrote over 25,000 of them), it comes as no surprise that many of his inventions dealt with this matter. For instance, afraid of the possibility that his letters might fall into hands other than those of their intended recipients, while he was secretary of state, Jefferson designed in 1792 to 1793 a wheel cipher to encode his writings and thus keep his

correspondence secret. An improved version of Jefferson's wheel, known as M-94, was used by the U.S. Army from 1922 to World War II. Jefferson invented a lap desk holding all that he needed, including a portable printing press, while his pantograph's three arms held three pens while he wrote a letter so that four copies of the same letter were simultaneously produced.

Jefferson's stay in Paris (from August 1784 to September 1789) proved to be most influential on him. These five years constituted a creative period in his life. In Paris, Jefferson was exposed to a multitude of written sources that he had never seen before and a host of intellectual luminaries. Most of his inventions, in their original form or in his improved versions, he would take with him to the United States at the end of his term in Paris.

Back in the United States, while he was secretary of state, he served on the Board of Arts that dealt with patent applications. The forerunner of what later became known as the U.S. Patent Office, it came into existence in 1790. Jefferson was on a three-member commission and acted as the first patent commissioner and the first patent examiner. He personally reviewed every application submitted from 1790 to 1793, which allowed him to keep up to date with the latest developments. Jefferson established strict criteria for granting a patent, which included utility, novelty, and creativity.

Curiously enough, in the light of his role, Jefferson disliked patents because he thought that they went against democracy in that they prevented the population as a whole from enjoying a given invention. While he accepted that inventors might make a profit from their creations, he was against creations having restricted use. However, in time, he came to slightly revise his views on these matters, because he understood that patents encouraged people to invent, since they stood to make a profit. Nonetheless, he took no patents on any of his own inventions. As Jefferson was in favor of the dissemination of information, he was also against having a patent covering all the potential, future uses of a product.

Given Jefferson's lifelong interest in agriculture, which he considered a vital science, it is only natural that he devoted much of his inventing zeal to the improvement of farming machinery and utensils.

Along with his son-in-law Thomas Mann Randolph, around 1794, Jefferson developed a board plow. Jefferson had been toying with his idea of a new, improved plow while he was in France. Already in 1788, he had some ideas about having a moldboard made of wood. The first unit was used on his estate at Monticello, in Virginia, in 1794. Jefferson claimed that it was "mathematically demonstrated to be perfect" and, committed as he was to letting humanity as a whole profit from an invention, he found pride in the fact that it could be reproduced by anyone. The growing popularity of iron moldboards prevented the widespread use of Jefferson's plow, although he had his moldboard made of iron from 1814 onward. James Mease's *Domestic Encyclopedia* (first published in 1803) included it.

Jefferson introduced the pedometer in America following his stay in France, although it is not known if he brought with him the original article or if he improved it and therefore introduced his own version of it. The pedometer, also known as the "Tomish meter" after Jefferson, was based on an idea of Leonardo da Vinci and used the movement of the pendulum. It was rudimentary and prone to error, though, as it provided an estimate rather than an accurate figure. Jefferson's love for books led him to develop a bookstand for holding up to five books.

Jefferson also turned his attention to interior designing and, thus, in Monticello, there were no bedsteads. Instead, beds were placed in alcoves between pairs of rooms so as to use space as effectively as possible. Jefferson improved the revolving Windsor chair too, an example of which can be still seen at Monticello. Committed to making daily tasks easier so that they would not be so time-consuming, Jefferson also turned his attention to home economics and domestic matters, as his invention of household items testifies to. For instance, he developed a new system of dumbwaiters—pipes in his Monticello home that allowed his servants to send wine bottles upward from the basement cellar to the dining room. Jefferson also designed automatic double doors in Monticello in 1804. The unique, in-floor mechanism made both doors open or close at the same time.

His inventions earned Jefferson international recognition. Among other things, his interest in agricultural improvement won Jefferson the gold medal of

the French Society of Agriculture as well as being offered an honorary membership from this institution and the British Board of Agriculture (1797). The Agricultural Society in Florence also granted him an honorary degree.

Jefferson greatly contributed to American natural history when he promoted the Lewis and Clark Expedition. The expedition, the first of its kind to cross the western United States and territories, ostensibly sought a Northwest Passage, or a waterway that led all the way across the continent. Though the expedition found no such passageway, it did catalog hundreds of native plants and animals, map new territory, and establish an American claim to land that belonged to the native people who lived on it. The expedition provided invaluable scientific information.

Benjamin H. Latrobe and Jefferson created a sundial in 1809, but Jefferson also designed the Great Clock at Monticello's entrance although Louis Leschot built it. After the clock was built, Jefferson invented a special folding ladder that, from the beginning of the 19th century onward, has been very useful in libraries all over the United States.

So large and complex is Jefferson's invention library that inventions other than his own are sometimes wrongly attributed to him. Thus, in popular culture, Jefferson is sometimes credited as the inventor of such a common American dish as "mac and cheese," although this is a fallacy. Jefferson did work on a pasta machine, though, based on one he had brought with him from France, where, during his service as U.S. ambassador, he found that macaroni was a very fashionable dish in Parisian society. Jefferson came to see development and technological progress as crucial to the development of the new nation. Jefferson was strict in granting new patents and ruled out applications in which the only difference with existing patents was a slight change or a new material used to produce the item in question.

Despite the fame that Jefferson received in his lifetime for his contribution to scientific progress, more recently his status as inventor has been questioned. Some claim that the label "inventor" is not accurately attached to Jefferson, as rather than invent, he improved already-existing products. For them, the term that better applies to Jefferson is "innovator" rather than "inventor."

Thomas Jefferson died on July 4, 1836, at his home in Monticello. He is buried there. His tombstone lists his many accomplishments but does not mention his passion for innovation and invention.

Lewis and Clark Expedition (1804–1806)

In 1803, President Thomas Jefferson asked Congress for money to fund a "Corps of Discovery." His intent was for a military team to explore and map the vast new Louisiana Purchase territory that the fledgling United States had just acquired. One of his top priorities was for the expedition to find an all-water route from mid-America to the Pacific, with rivers and a newly burgeoning canal system being essentially the "superhighways" of early America for transporting goods and people. By carrying the American flag overland to the Pacific Ocean, Jefferson also wanted the team to establish U.S. sovereignty over the Western territory and to establish trade agreements with indigenous people for the United States rather than the British, French, and Spanish.

However, under the watchful eyes of England, France and Spain, as well as Congress, Jefferson presented the goal of the Corps of Discovery in a somewhat different light. It was to be a scientific expedition in which Lewis and Clark would meticulously record observations about the animals, plants, geography, topography, and inhabitants of the virtually-unknown-to-Europeans territory through which they passed.

In addition to its extensive length, the scientific aspect would set Lewis and Clark's Corps of Discovery apart from previous explorations such as those by Robert de La Salle (1643–1687) as well as expeditions by contemporaries such as Zebulon Pike (1779–1813), in which scientific discoveries were not a priority.

In keeping with his scientific slant, Jefferson selected Army Captain Meriwether Lewis because of his vast knowledge of botany, natural history, mineralogy, and astronomy. Lewis then chose William Clark as second in command. With Jefferson's encouragement and patronage, the team leaders adopted the scientific method in preparing for the journey. Jefferson sent Lewis to Philadelphia to study medicinal cures under physician Benjamin Rush. The president also arranged for Lewis to be tutored by astronomer Andrew Ellicott in the use of the sextant and other means of utilizing the celestial bodies as navigational aids. Jefferson gave Lewis full access to his home library at Monticello, where Jefferson possessed what was said to be the world's largest library on the geography of North America.

Through the American Philosophical Society in Philadelphia, an expedition sponsor, Lewis and Clark received additional instruction in astronomy, botany, climatology, ethnology, geography, meteorology, mineralogy, ornithology, and zoology. All would come in handy during the expedition, where they would make contact with more than 70 tribes of Native American people and would go on to describe over 200 new plant and animal species.

After enlisting a team of 38 military men plus a few French boatmen and Lewis's dog, the voyage of discovery departed from St. Charles, Missouri, near St. Louis, on May 14, 1804. Sometimes moving up to 70 or 80 miles a day, the Lewis and Clark expedition would ultimately cover a grueling 8,000 miles over 28 months between 1804 and 1806.

Lewis and Clark began making detailed reports on what they encountered along their way West. They took scientific measurements and observations of the Missouri River, including its depth, current, and tributaries along with the inhabitants, plants, and wildlife to be found along its course. They would also go on to document their observations of the Rocky Mountains and the landscape of the Pacific Northwest.

Ultimately, Lewis and Clark's scientific observations would include descriptions of around 120 birds, fish, mammals, and reptiles. Soon after they departed, in what is today's Osage County, Missouri, they encountered and described their first animal that was then unknown to European science: the eastern wood rat. Other new animal species they encountered included bighorn sheep, black-tailed deer (or mule deer), buffalo, coyote, mountain beaver, mountain goats, pronghorn antelopes, white weasels, and various species of fox, rabbit, squirrel, wolf, and grizzly bears. The grizzlies became a topic of special note when the fierce animals attacked the group and were so tough that even several rifle shots were unable to kill them. The team recorded encountering so many buffalo that at one point that they had to club them out of the way. Lewis and Clark became fascinated with the prairie dogs that built huge underground villages and tended to outwit the humans who tried to trap them.

Lewis and Clark did not limit themselves to description. Shooting or otherwise catching an individual of each species of wildlife, they measured and described the specimen and then preserved it for shipment back to President Jefferson. Their zoological specimens included live animals as well as bones, horns, skeletons, skins, talons, and teeth. Among the live animals Lewis sent to Jefferson was a barking squirrel, or black-tailed prairie dog, which lived out the rest of its days at the White House.

Jefferson directed Lewis and Clark to pay special attention to the soil and the types of vegetables produced in different areas and climates. He believed that having a greater botanical knowledge of the continent's bounty would contribute to the world's food supply and would determine which plants were beneficial to humans. At Monticello, Jefferson planted seeds from the Lewis and Clark expedition, including "Missouri hominy corn," which he cultivated and studied, later reporting that the Indian corn he grew was an excellent source of food.

The Corps of Discovery team described hundreds of plants that were new to it, with Lewis writing extensively about the botany of the Pacific Northwest during a winter encampment on the Columbia River. Several botanical specimens discovered by Lewis and Clark were named after them: the pink *Clarkia pulchella*,

also known as pinkfairies, and the white *Philadelphus lewisii*, or Lewis's mock orange (today the state flower of Idaho). Their discoveries also included the future state flowers of Oregon (the Oregon grape, also known as the holly-leaved barberry or *Mahonia aquifolium*) and Montana (bitterroot, or *Lewisia rediviva*), as well as the state grass of Montana (bluebunch wheatgrass, or *Agropyron spicatum*).

Lewis and Clark collected plant specimens, recording information on growth, habitat, and uses by Native Americans. Lewis especially showed a talent for observation and lyrical writing in his essay about camas, or quamash, an important food plant for the Nez Perce tribe. He carefully noted the plant's environment and physical structure along with a description of Nez Perce women harvesting and preparing the camas to play its role in the tribe's diet.

The observations and reports by Lewis and Clark formed the basis for the first major scientific publication to describe and illustrate plant life west of the Mississippi River. They also collected plant samples and pressed them. The botanical specimens that Lewis and Clark sent back east were housed at the American Philosophical Society in Philadelphia, later finding a permanent home at Philadelphia's Academy of Natural Sciences, where their plant collection still exists today.

The Lewis and Clark team also made the first known attempt at a scientifically systematic record of the meteorology of the American West. In addition, they attempted to determine the latitude and longitude of significant geographical points. They determined the true course of the Upper Missouri River and its major tributaries. They disproved the prevailing theory that only a short portage separated it from the Columbia River, and they also found that the Columbia was hardly the short coastal river it was thought to be but a significant waterway similar to the Missouri itself. Lewis and Clark also discovered that neither the Missouri nor the Columbia was navigable to its source, as many believed they were at the time.

The expedition observed and recorded geological findings such as types of rock formations. In a discovery of great significance, they found through personal experience that neither the Rocky Mountains nor the Cascades were small, easily crossed mountain ranges

as was believed at the time. The discovery that the Rockies and Cascades were major barriers would modify the prevailing concept about how the American West would be traveled and settled.

For the most part, Lewis and Clark's team passed through country that no European Americans had yet seen. Clark, with some experience via army mapping and surveying, made a major scientific contribution in the field of cartography. The maps that he and Lewis created, though relatively crude, greatly enriched geographical knowledge of the western United States and would go on to stimulate advances in mapmaking. Their maps included names of streams and natural features. They also provided the first accurate description of the Rocky Mountains as well as the sources of the Columbia and Missouri Rivers. They were the first European Americans to cross the Continental Divide and to experience the grandeur of Yellowstone.

Yet for all their contributions to the "hard" sciences, one noteworthy aspect of the Lewis and Clark expedition is an intriguing footnote to the social sciences. An African American slave named York (1770–1831) and a Shoshone woman named Sacagawea (1788–1812) also accompanied the Corps of Discovery. On November 24, 1805, when the expedition reached the spot where the Columbia River emptied into the Pacific Ocean, Lewis and Clark held a vote among all the members of the group to decide where to settle for the winter. Both Sacagawea and York were permitted to vote, with their votes counting equally among those of the others. It was the first and only known instance of a woman and an African American having the opportunity to vote in the United States and would remain so for the better part of a century.

Primary Document: Excerpts from the Journal of the Lewis and Clark Expedition (1805, 1806)

The first excerpt here is from Meriwether Lewis's expedition journal from May 1, 1805. The expedition was heading west from Fort Mandan to the Pacific and by May had made it to present-day Montana. Lewis recorded a variety of subjects in his journal, including meticulous examinations of new species of animals. The following is a description of a waterbird from the Milk River. The second excerpt is from the trip home from the Pacific back through Montana and describes a ground squirrel.

May 1st 1805.
Shannon killed a bird of the plover kind the weight one pound.—eye black percing and prominent [EC: avocet (*Recurvirostra*)]

Measure	F.	Inchs
from the tip of the toe to the extremity of the beak	1	10
from tip to tip of wing when extended	2	5
length of beak		3 ⁵ / ₈
length of tale		3 ¹ / ₈
length of leg (thy,) and toe		10

the legs are flat, of pale skye blue colour and but slightly imbricated. the second joint, as low as the mustle extends is covered with feathers which is about half it's length. it has three toes on a foot connected by a web. there is also a small toe on each foot placed about the eighth of an inch up the leg behind. the nails are black and short and those of the middle toes ar singular—there being two nails on each the one above the other the upper one the longest and sharpest.— the tale contains eleven feathers of the same length of a bluish white colour. the body and under side of the wings except the large feathers of the 1 & 2cd joints of the wings are white, as are also the feathers of the upper part of the 4th joint of the wing. and some of those of the 3rd adjoining.— the large feathers of the pinion or first (joint) & the second joint (and a part of those of the third on the) are black; a part of the larger feathers of the third-joint on the upper side and all the smaller feathers which cover the upper part of these joints ar black; as

are also the tuft of long feathers on each side of the body above the joining of the wing, leaving however a stripe of white between them on the back. the head and neck are shaped much like the grey plover, and is a light (yellowish) brickdust brown. the beak is black and flat, largest where it joins the head and from thence tapering every way gradually to a very sharp point the upper beak being ¹/₈ of an inch the longest turning down at the point. the nostrils are parrallal with the beak and are long narrow and connected. the beak is curved and invirted; the Curvature being upwards in stead of downwards as those of most birds are—the substance of the beak is as flexible as whalebone and (to all appe) at a little distance precisely resembles that substance. their note is like that of the common whistling or grey plover tho' reather louder, and more varied, and their habits are the same with that bird so far as I have been enabled to learn, with this difference however that this bird sometimes lights in the water and swims.—it generally feads about the shallow bars of the river; to collect it's food, it immerces it's beak in the water, and thows it's head and beak from side to side at every step it takes.

Tuesday July 1st 1806.

The little animal found in the plains of the Missouri which I have called the *barking squirrel* weighs from 3 to 3½ pounds. it's form is that of the squirrel. it's colour is an uniform light brick red grey, the red reather predominating. the under side of the neck and bely are lighter coloured than the other parts of the body. the legs are short, and it is wide across the breast and sholders in proportion to it's size, appears strongly formed in that part; the head is also bony muscular and stout, reather more blontly terminated wider and flatter than the common squirrel. the upper lip is split or divided to the nose. the ears are short and lie close to the head, having the appearance of being cut off, in this particular they resemble the guinea pig. the teeth are like those of the squrrel rat &c. they have a false jaw or pocket between the skin and the mustle of the jaw like that of the common ground squrrel but not so large in proportion to

their size. they have large and full whiskers on each side of the nose, a few long hairs of the same kind on each jaw and over the eyes. the eye is small and black. they have five toes on each foot of which the two outer toes on each foot are much shoter than those in the center particularly the two inner toes of the fore feet, the toes of the fore feet are remarkably long and sharp and seem well adapted to cratching or burrowing those of the hind feet are neither as long or sharp as the former; the nails are black. the hair of this animal is about as long and equally as course as that of the common grey squirrel of our country, and the hair of the tail is not longer than that of the body except immediately at the extremity where it is somewhat longer and frequently of a dark brown colour. the part of generation in the female is placed on the lower region of the belly between the hinder legs so far forward that she must lie on her back to copolate. the whole length of this animal is one foot five inches from the extremity of the nose to that of the tail of which the tail occupyes 4 inches. it is nearly double the size of the whistling squirrel of the Columbia. it is much more quick active and fleet than it's form would indicate. these squirrels burrow in the ground in the open plains usually at a considerable distance from the water yet are never seen at any distance from their burrows. six or eight usually reside in one burrow to which there is never more

than one entrance. these burrows are of great debth. I once dug and pursued a burrow to the debth of ten feet and did not reach it's greatest debth. they generally associate in large societies placing their burrows near each other and frequently occupy in this manner several hundred acres of land. when at rest above ground their position is generally erect on their hinder feet and rump; thus they will generally set and bark at you as you approach them, their note being much that of the little toy dogs, their yelps are in quick succession and at each they a motion to their tails upwards. they feed on the grass and weeds within the limits of their village which they never appear to exceed on any occasion. as they are usually numerous they keep the grass and weeds within their district very closely grazed and as clean as if it had been swept. the earth which they throw out of their burrows is usually formed into a conic mound around the entrance. this little animal is frequently very fat and it's flesh is not unpleasant. as soon as the hard frosts commence it shuts up it's burrow and continues within untill spring. it will eat grain or meat.

Lobster Trap

Ebenezer Thorndike of Swampscott, Massachusetts, invented the lobster trap in about 1808 as a practical way to catch lobsters. His revolutionary wooden trap allowed fishermen to lower it onto the sea floor. A rope extending from the trap to the water's surface connected it to a buoy with the fisherman's identification. The bread-box-size trap had a one-way, funnel-shaped entrance called a "door." It allowed the lobster to enter the trap but not exit it.

Lobster traps today generally have two compartments. The first compartment, known as the "kitchen," lures the lobster inside with a hanging, fish-filled mesh bag. The funnel-shaped entrance prevents the lobster from retreating once it eats the bait. Cornered, it climbs into the second compartment known as the "parlor." It

remains there until the fisherman retrieves it. Modern lobster traps have escape vents for undersized lobsters and biodegradable escape hatches in case an occupied trap becomes lost. The lobster trap remains in almost the same configuration as when Thorndike invented it, except the wood has been replaced with metal wire to ensure a lighter-weight, easily stackable contraption that does not erode in salt water.

Lowell Mill System

Prior to the Industrial Revolution (1820–1870), textiles were produced in the home. With the advent of industrialization, however, home production dwindled and textiles began to be produced largely by factories. In 1826, several factory owners purchased Chelmsford, Massachusetts, as the site for a manufacturing town. This portion of Chelmsford was renamed Lowell after Francis Cabot Lowell (1775–1817), an American businessman who improved American spinning and weaving machines and founded the first mill in America where raw cotton was processed and converted into cloth in the same building. Lowell, Massachusetts, is significant to the history of American industrialization because the town was entirely based around mill life. The mills employed primarily female workers, who lived in local boarding houses, shopped at company stores, and engaged in company-approved leisure-time activities, making Lowell the first company town.

The Lowell mill system was unique in that it purposefully hired young women, both because women were paid less and because young men were still

working on family farms in the early 1800s. Women workers came from New England farms and were between the ages of 15 and 25. Many came to the mills to help support their families or to send their brothers to college. Most women signed up for short terms of employment, averaging three years, and left to marry, return home, or emigrate west. During the 1850s, Lowell factory owners began hiring female Irish immigrants who had fled to the United States to escape the Irish Potato Famine (1845–1851).

By 1836, Lowell was the home to over 17,000 people, most of whom were female mill workers. Work began at 5:00 a.m. and ended at 7:00 p.m., with two breaks lasting a half hour each. In 1834, the company announced it would cut wages. Women workers took to the streets in protest. Though the strike did not raise wages, it did provide female workers with strike experience. In 1836, owners once again announced that wages would be cut. Also, workers would pay housing and meals, which had previously been partially paid for by the factory, in full. Factory workers again went on strike. Mills were forced to shut down, and between 1,200 and 1,500 women and girls marched through town in protest, singing songs as

The women who worked in the Lowell Mills in the early 19th century were America's first factory workers. The Lowell Mill System included spinning, weaving, and dyeing factories, as well as housing, religious services, and entertainment for "lady operatives." (Library of Congress)

they walked. At a time when women rarely spoke in public, Lowell women made speeches against their employers' decision to reduce wages.

Skilled factory laborers led the landmark 1836 strike. Workers had correctly assumed that if the most central workers in the factory walked out, it would be forced to close. The strike lasted for two weeks, and the Factory Girls' Association was founded with 2,500 members. The Association's constitution maintained that any woman who worked in the mills and had a good reputation could join the association. Similar to a labor union, the Factory Girls' Association demanded better conditions for its members. Key to its demands was that factory owners not punish members of the Factory Girls' Association. The 1836 strike concluded with little significant change in worker's conditions, but the factory owners agreed to continue paying a partial fee for lodging.

In 1845, factory workers were still fighting for fair wages and board. Recognizing that the Factory Girls' Association was not strong enough to address these issues, in January 1845, 12 factory workers organized the Lowell Female Labor Reform Association (LFLRA), the first union of working women in the

United States. Like the Factory Girls' Association, the LFLRA campaigned to protect workers' wages and for the 10-hour workday. Within six months, membership had grown to 500. Both the Factory Girls' Association and the LFLRA served notice to factory owners that their female workforce would be neither passive nor submissive about its rights as workers. In the 1840s and 1850s, female unions would spread to factory towns in Manchester, Massachusetts; Dover, New Hampshire; and Fall River, Massachusetts.

Primary Document: Description of the Life of a Mill Girl from the Lowell Offering (1845)

The following is an anonymously authored description of the life of a Lowell Mill girl, first published in volume V of the Lowell Offering in 1845. The reality of cotton mill work fell well short of the propaganda generated by mill owners, which portrayed mill work as wholesome, safe, and generally pleasant.

Much has been said of the factory girl and her employment. By some she has been represented as dwelling in a sort of brick-and-mortar paradise, having little to occupy thought save the weaving of gay and romantic fancies, while the spindle or the wheel flies obediently beneath her glance. Others have deemed her a mere servile drudge, chained to her labor by almost as strong a power as that which holds a bondman in his fetters; and, indeed, some have already given her the title of "*the white slave of the*

North." Her real situation approaches neither one nor the other of these extremes. Her occupation is as laborious as that of almost any female who earns her own living, while it has also its sunny spots and its cheerful intervals, which make her hard labor seem comparatively pleasant and easy.

Look at her as she commences her weekly task. The rest of the sabbath has made her heart and her step light, and she is early at her accustomed place, awaiting the starting of the machinery. Every thing having been cleaned and neatly arranged on the Saturday night, she has less to occupy her on Monday than on other days; and you may see her leaning from the window to watch the glitter of the sunrise on the water, or looking away at the distant forests and fields, while memory wanders to her beloved country home; or, it may be that she is conversing

with a sister-laborer near; returning at regular intervals to see that her work is in order.

Soon the breakfast bell rings; in a moment the whirling wheels are stopped, and she hastens to join the throng which is pouring through the open gate. At the table she mingles with a various group. Each despatches the meal hurriedly, though not often in silence; and if, as is sometimes the case, the rules of politeness are not punctiliously observed by all, the excuse of some lively country girl would be, "They don't give us time for *manners*."

The short half-hour is soon over; the bell rings again; and now our factory girl feels that she has commenced her day's work in earnest. The time is often apt to drag heavily till the dinner hour arrives. Perhaps some part of the work becomes deranged and stops; the constant friction causes a belt of leather to burst into a flame; a stranger visits the room, and scans the features and dress of its inmates inquiringly; and there is little else to break the monotony. The afternoon passes in much the same manner. Now and then she mingles with a knot of busy talkers who have collected to discuss some new occurrence, or holds pleasant converse with some intelligent and agreeable friend, whose acquaintance she has formed since her factory life commenced; but much of the time she is left to her own thoughts. While at

her work, the clattering and rumbling around her prevent any other noise from her attention, and she *must think*, or her life would be dull indeed.

Thus the day passes on, and evening comes; the time which she feels to be exclusively her own. How much is done in the three short hours from seven to ten o'clock. She has a new dress to finish; a call to make on some distant corporation; a meeting to attend; there is a lecture or a concert at some one of the public halls, and the attendance will be thin if she and her associates are not present; or, if nothing more imperative demands her time, she takes a stroll through the street or to the river with some of her mates, or sits down at home to peruse a new book. At ten o'clock all is still for the night.

The clang of the early bell awakes her to another day, very nearly the counterpart of the one which preceded it. And so the week rolls on, in the same routine, till Saturday comes. Saturday! the welcome sound! She busies herself to remove every particle of cotton and dust from her frame or looms, cheering herself meanwhile with sweet thoughts of the coming sabbath; and when, at an earlier hour than usual, the mill is stopped, it looks almost beautiful in its neatness.

Milling Machine

Eli Whitney is best known for his invention of the cotton gin, but for many years and in many circles, he also was credited with inventing the milling machine. However, while the noted machine tool historian Joseph W. Roe has credited Whitney with inventing the first milling machine around 1818, many subsequent historians acknowledge that while Whitney was an important figure in the development of the milling machine, there is sufficient evidence to indicate that a number of inventors were working on the concept at the same time. Thus, it is difficult to give Whitney exclusive or full credit. More likely, he belongs in the group of inventive figures who composed, however informally and unconsciously, a collaborative network that in the end produced the important machine.

A milling machine is essentially a form of metal-cutting machine. The kind of work it was subsequently developed to do was at the heart of the individual handmade process that characterized the efforts of early craftsman. Indeed, before the machine was developed, a craftsman would have to individually cut each metal piece to the proper size and configuration, and then the edges would have to be smoothed before assembly—of whatever the final product might have been—could be undertaken. This long and laborious task was part of the reason it took so long for handmade products to be completed, as well as why each was so distinctive.

In contrast to this individualized, labor-intensive process, the milling machine was a device similar to a lathe in that it featured a rotating cutting tool that allowed a machinist to produce a succession of almost

identical items. This left the skilled craftsman with only the comparatively smaller task of smoothing with a file the edges of each individual piece, a process that was still needed to provide a form of polish. This new approach made the process both easier and faster than when the work had been done by the individual operators, who themselves needed to be more technically skilled than the laborer who would now operate the milling machine. In addition, the milling machine allowed for the creation of a series of pieces all the same basic size. In fact, in the early years of their operation, the milling machine was hailed for the way it reduced subsequent hand filing while also bringing a consistency to the size and shape of the pieces. Indeed, the machine's capabilities fit right in with the broader efforts that Whitney and others were developing in regard to interchangeable parts. While the milling machine's development lagged behind the efforts of those working with interchangeable parts, the ultimate development of the milling machine would help further the whole mass production effort fueled by the development of interchangeable parts.

As to the matter of credit, machine tool historian Joseph W. Roe is the man most responsible for tapping Whitney as the inventor of the milling machine. Relying largely on the famous Whitney Machine, an invention initially believed to have been created in 1818, he pronounced Whitney the “father of the milling machine.” However, later work by historians, including Robert Woodbury, Merritt Roe Smith, and Edwin Battison, point to a wider-ranging effort, one that places Whitney among a group of fellow inventors, all of whom were going in the same direction and working toward the same end. At the same time, it is distinctly possible that Whitney's outsized reputation as the inventor of the cotton gin, a major force behind the development of interchangeable parts, not to mention being nationally renowned as the man who, in the words of his benefactor, Mrs. Nathanael Greene, “could fix anything,” coupled with his well-established skills as a salesman and marketer, served to overshadow the efforts of others.

In the end, enough questions exist—including whether the model on which Roe has based his determination, and which was supposedly built in 1818, was even built in that year—and enough counterevidence

has been uncovered to make clear that while Whitney played an important and substantive role in the development of this important machine, neither he nor anyone else can truly claim the mantle of sole inventor of the technological advance that the milling machine represented.

Morey, Samuel (1762–1843)

An American inventor and engineer, Samuel Morey acquired over 20 patents in his lifetime. His most notable work was done on two types of engines: the steam engine and the internal combustion engine. However, Morey received little recognition for his innovations. His design of what he called a “vapor engine” is considered one of the first internal combustion engines. Upon creating his first functional vapor engine, he predicted that travel could, in the very near future, be made faster and cheaper. Morey also performed many experiments using a variety of materials for combustion, including pumpkin, oils, coal, rosin, and many seeds. The records of these experiments proved useful to pure scientists such as Gay-Lussac, the well-known chemist.

In 1793, Morey received his first patent for a steam-powered spit that would mechanically rotate rotisserie food, using steam power as it cooked. Because his father owned a ferry, Morey saw the benefits of a steam-powered boat. In the early 1700s, Jonathan Hull had already attempted steam-powered watercraft, but his experiments failed. Like they did at many revolutionary ideas, people laughed at the idea of using steam to propel boats, but Morey predicted its success and set to work. His first boat utilized a

forward-mounted paddle wheel and a steam-powered engine. Using this, he successfully made trips up and down the Connecticut River, showing that the concept was credible. Eventually, Morey designed a boat that made use of two side-mounted paddles. Under steam power, the boat could attain speeds of four miles per hour. Confident in his design, he sought investors but had little success. Robert Livingston originally offered a significant amount of money if Morey could double his boat's speed; however, in the end, his money went to one Robert Fulton (whom Morey claims stole aspects of his design).

Morey abandoned the steam engine in favor of his vapor engine idea. Upon discovering the potential of combusting turpentine, he designed an engine with two cylinders, valves, cams, and a carburetor similar to modern-day internal combustion engines. The main difference in his vapor engine is that the combustion wasn't the direct source of power; it had a more complex and convoluted design, causing it to be less efficient. However, this didn't stop Morey from exhibiting this engine in the first American automobile ride.

Samuel Morey died in 1843 and was buried in Fairlee, Vermont. Although neither his steamboat nor his internal combustion engine were used commercially or given much credit in his day, his work has garnered him the attention of historians of science and technology.

Multitubular Boiler

The multitubular boiler was created by Nathan Read in 1788. Its main purpose was to sustain higher pressure within a steam engine. The boiler is thus essential to steam engine operation.

Multitubular or locomotive-type boilers operate when fuel is burned in a firebox to create heat; the firebox is surrounded by a jacket of water tubes and connected to a boiler shell. Heated gas from the fire tubes create saturated or "wet" steam, which rises and is collected in a steam dome. This steam is then directed into the engine's cylinders or turbines to create mechanical work. Excess gas is generally let out through a chimney. The multitubular boiler represents an improvement on earlier boilers because it used large numbers of small tubes, thereby increasing heat transfer and significantly improving the rapidity of steam production.

These boilers came in both horizontal and vertical types. Modern steam engines have added a number of improvements to the 19th-century boiler design, making the engines much safer and more efficient. Boiler explosions, which used to kill hundreds and even thousands of people each, are now prevented with safety valves and fusible plugs.

National Road

At the dawn of the 19th century, the biggest barrier to the progress of the nation was the lack of a transportation system connecting the East Coast to the then western frontier. There was no water connection, as the Allegheny Mountains separated the Potomac and Ohio Rivers. Lack of transportation limited the growth of western industry and agriculture. Following an old Indian trail, George Washington had been one of the

The National Road, also known as the Cumberland Road, just outside Brownsville, Pennsylvania, in 1910. Built between 1811 and 1837, the road was a main route for settlers traveling West. (Library of Congress)

first settlers to make the portage between the Potomac and Ohio Rivers as a young surveyor in 1753. The path was known as Nemacolin's Trail after the Delaware Indian chief. The trail connected Maryland and Pennsylvania via the Cumberland Gap in the mountains. A few years later, Washington helped build a rough road along this trail for General Braddock's failed expedition to take the headwaters of the Ohio (present-day Pittsburgh) from the French. The trail, known as Braddock's Road (today's Route 40), and its competing trail, known as Boone's Trail, were the only paths west at the start of the 1800s. Forbes Road was a longer trip that went through Pennsylvania to Philadelphia.

One of America's first highways in the 1730s was known as "the Great Philadelphia Wagon Road." German and Swiss families set up a transportation network between Philadelphia and Lancaster to support the extensive trade. The road was built privately on the

belief that it would foster trade and wealth. It was America's first toll road. This first turnpike allowed German farmers to become wealthy, supplying both Philadelphia and Lancaster. The rise of capitalism surrounding the turnpike rivaled that of the shipping ports of New England. At the western terminus of the road, German craftsmen developed the Conestoga wagon, also called the "prairie schooner." These giant freight wagons were named after Conestoga Creek at Lancaster. They were watertight and used iron belts around their wooden wheels as tires. Six- to eight-horse teams pulled these freight wagons. They moved in convoys of up to 100. By the 1740s, around 10,000 Conestoga wagons were in use. The Germans went into breeding "Conestoga" horses to further improve the overall transportation system. Lancaster not only moved farm products to Philadelphia but also gathered furs and whiskey from the western frontier for shipment to Philadelphia and on to Europe. The turnpike became a

vital link in the Scotch-Irish trading network of furs, whiskey, tobacco, ginseng, and grain. Philadelphia became the nation's major port because of this turnpike. The word "turnpike" came from the use of wooden pikes to mark turns and direction. This turnpike played a key role in the development of whiskey production in western Pennsylvania. In the early 1800s, Federalists were calling for a national road.

In 1794, the federal army was sent on the old Braddock Road through the Cumberland Gap to put down the Whiskey Rebellion. Sinkholes, poor drainage, and old stumps slowed the army. Ironically, Albert Gallatin, a participant in the Whiskey Rebellion, became the National Road's biggest supporter as Thomas Jefferson's secretary of the Treasury. In 1806, a bill was introduced by Kentucky congressman Henry Clay to build a road through the Cumberland Gap to connect the Ohio River to the East. More than anybody, Clay was weary of the monthlong trip from Lexington, Kentucky, on the Ohio River to Washington. Virginia and Maryland favored a road that would choose their ports over those of New York and Philadelphia. While Jefferson signed the bill in 1806, political arguing over the route continued. In 1811, Congress finally assigned contracts for the construction. Congress had also decided to bypass Pittsburgh, with the National Road going through Wheeling, a decision that was probably due in part to Pittsburgh's role in the Whiskey Rebellion.

Construction of the first leg of the road from Cumberland, Maryland, to Wheeling, West Virginia (130 miles), took six years. This first road had a 66-foot right-of-way with a 20-foot roadbed. It tapered from the centerline for drainage and at the center had 18 inches of crushed stone. Wages for road workers ranged from 12 to 80 cents a day. It was tough work through the Pennsylvania mountains, and many streams had to be crossed. Costs were as high as \$13,000 per mile in this difficult stretch. The first economic benefit was the use of the road for federal mail to the frontier. The early road was a combination of leveled earth and stone. In areas of heavier traffic, wooden planks were often used (many of these areas retain the name "plank" even today). In the 1820s, the road was resurfaced using a layer of crushed stone.

John Macadam invented the method, which became known as "macadamization."

The road progressed along the present Route 40 from Wheeling to Vandalia, Illinois. The Ohio portion from Wheeling followed "Zane's Trace," a federal horse path financed by the federal government back in the 1790s to increase trade. In 1834, Democratic President Andrew Jackson vetoed a bill from Clay, of the Whig Party, to extend the road again into his home state of Kentucky. In addition, Jackson turned most of the eastern part of the road over to the states. The states turned it into a toll road. Tollhouses were placed every 15 miles, and a toll of two to five cents was charged based on the type of cargo and estimated weight (a practice that still exists). In the 1830s, an express wagon could make 150 miles a day on the road. Average travel was slower, with nightly stops at major inns along the road.

The National Road advanced the fields of civil engineering, road building, and bridge building. Both the Federalists and the Democrats believed in the need for government involvement in building infrastructure but disagreed on who should pay for and maintain the roads. The main opposition to the road was based on regional politics because some sections of the country, like the South, had little benefit from it. New England opposed it because it strengthened more southerly ports such as Baltimore. In general, however, road building had strong support throughout America. The first accepted local taxes in America were for roads and schools. Tolls, however, proved less popular as travelers developed trails around tollgates known as "shunpikes." The success of the National Road to expand business made road building an important part of the emerging Whig Party, which was dedicated to the economic prosperity of America.

Odometer

Benjamin Franklin invented the three-wheel odometer in 1749 to measure the length of postal roads.

King George III appointed Franklin the postmaster of Philadelphia in 1737 and deputy postmaster general for North America in 1753. Given the fast growth of the British colonies in the 18th century, Franklin felt the necessity to improve the postal system to facilitate communication and trade. The mail service also needed to be upgraded. A high percentage of the mail was lost or stolen, and in other cases, it simply took too long.

Before Franklin's postal appointment, slaves, friends, and even sailors delivered letters from town to town on a voluntary basis. Post offices were set up in pubs and coffeehouses. Franklin wanted independent post offices throughout the colonies, and he needed to know how far they were apart so as to incorporate logistical efficiencies.

While the concept of the odometer dates back to ancient times, Franklin created a unique and much-improved version. The device registered the distance traveled when it was attached near the wheels of the carriage. Based on the circumference of the wheel and the number of revolutions required to travel a mile, the distance traveled could be calculated. When activated from a carriage wheel having a circumference of 13 and one-fifth feet, a mile was completed every 400 revolutions. If fixed to the top of the front axle at the right-hand side, it was easily set in operation by a nub-type projection on a hub or spoke, and the dials were readily detectible to both the driver and the passenger.

As noted above, the odometer consisted of a series of cogs and wheels that measured distance. On the top of the works was a flat metal plate that had a series of three circles. The left circle had a T above it and had numbers from 10 to 1 running counterclockwise around the circle, with "10" in the noon position. The circle was white with black Arabic numerals. At the center circle was a brass arrow—the one on the left was completely missing, and the one on the right was only a flat disk. The odometer was made of iron and brass and painted in light gold. It was one and two-thirds inches

in height, six and seven-eighths inches wide and four and one-quarter inches long.

By using the odometer to measure distances and creating other innovations in the postal system, Franklin was able to create a profit for the postal service by his fourth year in office. He was able to introduce night travel for postal riders, have mail delivered between Philadelphia and New York in a day, and have the reply come back the next day. Most important, these modernizations aided in significantly improving the mail service and integrating the distant regions of the colonies. It began the process of fortifying the strewn colonies into one unified country: the United States of America.

Patent and Copyright Statutes

It is amazing that the young nation of the United States put such emphasis on the protection of copyrights and patents. However, this focus would lead to America's greatest period of creativity and invention. Without the protection of intellectual rights, it is impossible for capitalism to flourish. Two of the Founding Fathers, Thomas Jefferson and Benjamin Franklin, attributed the growth of the nation to the spread of the useful arts. In 1783, as the Continental Congress considered the Articles of Confederation, a number of American authors, including Noah Webster, petitioned the Congress "that nothing is more properly a man's own than the fruit of his study, and that the protection and

security of literary property would greatly tend to encourage genius and to promote useful discoveries.” Jefferson, an inventor himself, took particular interest in copyright and patent law.

The colonies had had copyright and patent laws in place since the 1600s. Early colonial law was based on English law, which allowed for royal monopolies when the Crown chartered protection for the inventor; however, much of the profit would go to the Crown. The view was that inventions were the property of society, to be managed by a monarch. In the colonies, colonial courts could offer protection. The first colonial patent was issued to Joseph Jencks for the production of scythes in 1646. The General Court of Massachusetts chartered Jencks’s patent. In 1710, the Statute of Anne gave protection for a fixed period of usually 14 years. The Statute of Anne would become the basis for American patent and copyright law. Prior to 1790, the colonies and the states continued the practice of granting monopolies as a reward, but this actually reduced creativity. The state of New York, for example, gave John Fitch a steamboat monopoly in 1787 (but it would be repealed by federal law; see article 8 of the Constitution). Challenges to patents were possible but were debated among politicians as to their validity. Such a system favored the well known and wealthy. Most colonial inventors chose to keep their improvements secret rather than apply under a weakly enforced colony law.

At the Constitutional Convention of 1787, James Madison championed the need for federal protection versus protection by individual states. Intellectual property ownership was considered a basic right from our beginning as a nation. Copyright and patent law was authorized by the U.S. Constitution in Article I, Section 8, Clause 8, which states: “The Congress shall have the Power . . . To promote the progress of science and useful arts, by securing for limited times to Authors and Inventors the exclusive right to their respective writings and discoveries.” There was a debate between the Federalist James Madison and Jefferson. Jefferson wanted to encourage invention but feared the monopolies that might result from patents. Madison preferred unlimited periods of protection until the death of the inventor, while Jefferson argued

for a maximum of 14 years. This debate continues to this day.

In 1790, Congress passed the Copyright Act and the Patent Act. The Patent Act was meant to encourage creativity in the useful arts. These acts were unique in the world, offering an inventor for a time an intrinsic right to profit from his invention under protection of the law. It went far beyond British law, which had focused on the rights of society versus those of the inventor. British inventors’ rights were dependent on the prerogative of the monarch. American law now made the ownership of intellectual property an individual right. This was a break from English law that looked at invention as the property of society. It would inspire a wave of immigration by craftsmen and the European middle class to come to America as entrepreneurs. These American acts extended no protection to British copyrights, which allowed many machine- and toolmakers to bring their processes to America.

The Patent Act of 1790 named Secretary of State Thomas Jefferson as patent examiner. He proved a tough enforcer. Once reviewed, a patent received the signatures of the attorney general and the president. The inventor was charged a fee of around four dollars (a fairly large sum at the time). The first U.S. patent was given to Samuel Hopkins of Vermont for the improvement in the manufacture of potash (a necessary ingredient in soap and gunpowder). The duties of patent examiner soon overwhelmed Jefferson. The Patent Act, like the Copyright Act, allowed for protection for 14 years, with renewal possible for another 14 years. Another concern of Jefferson’s was the possibility of frivolous lawsuits preventing the use of improvements. In fact, Jefferson would be sued over one of his gristmill improvements and was forced to pay American superinventor Oliver Evans.

Jefferson was totally in charge of enforcing the new law. Jefferson demanded extensive proof that an invention was truly an improvement. He often demanded demonstrations and experiments as proof. He often requested the building of models to ensure the functioning of bigger projects. One example of his thoroughness was on the application of Jacob Isaac’s process for distilling freshwater from seawater. The idea was complex, and Jefferson appointed a board of scientists to review it. The board included famous American glassmaker Casper Wistar and astronomer

David Rittenhouse. Finally, after extensive testing, the patent was denied. The rigorous evaluation of patents made the American approach very unique in the world. Jefferson continued to improve the patent process. In 1793, the act was revised at his recommendation to establish a State Department clerk to aid in patent review. A full office of clerks was established in 1802. More so than any other person, Jefferson is responsible for American patent law and enforcement, which tries to balance individual rights, monopoly abuse, and the good of society. It was a unique balance that set the stage for a 200-year boom in American creativity. By the 1820s, the United States had issued 535 patents compared to 145 patents in England, which was the greatest industrial power on earth at the time.

Practical Ocean Navigation

Navigating the oceans in the 18th century was not easy. Contemporary navigation manuals contained inaccurate data. Methods to plot a ship's course were complicated and sometimes just educated guesses. Nathaniel Bowditch (1773–1838) was not a career sailor, but he used his mathematical expertise to correct inaccuracies in the primary manual of the day and to develop a navigational guidebook that relied on logarithms, logic, and accuracy.

When Bowditch was 10 years old, his family could not afford to continue to send him to school, so he worked for his father and studied on his own. He taught himself algebra and calculus and learned French and Latin so he could read advanced math books. Bowditch

became an apprentice clerk on a ship that sailed from Salem, Massachusetts, when he was 22 years old. While at sea for a year, he studied navigation.

The leading navigation manual at the time, *The New Practical Navigator* by John Hamilton Moore, was first published in 1772 in England. Bowditch studied the book's navigation tables and found many errors that could put a ship off course. While at sea, Bowditch corrected these mathematical miscalculations.

The American printer of *The New Practical Navigator*, Edmund Blunt (1770–1862), published an edition with those corrections. He decided that there were so many changes, he would publish a new edition of the book with corrected charts and navigation tables as well as information that American sailors would find useful. While *The New Practical Navigator* included instructions to sail from England, this edition included how to sail from the United States.

The New American Practical Navigator, published in 1802, included a glossary of nautical terms defined so any sailor could understand them. Chapters included discussions of piloting and sailing techniques, logarithmic tables needed for navigation, geographical terms, and how to adjust a sextant, use a compass, and calculate latitude. There was a chapter with directions for how to sail from the United States to India. It was and is considered a practical, functional encyclopedia of navigation. It is still used today.

For his innovative work on navigation, Bowditch received honorary degrees from Harvard University: master of arts and doctor of laws. The U.S. government bought the copyright to *The New American Practical Navigator* in 1866 and changed its title to *The American Practical Navigator* in 1880. Over 50 editions have been published since, with updated and revised information as technology has improved navigation techniques. The pdf (portable document format) file of the book is available online for free.

Report on Manufactures (1791)

The *Report on Manufactures* (also called *A Treatise on Manufacturing*) is considered the magnum opus of Alexander Hamilton, the first secretary of the Treasury. It was presented to Congress on December 5, 1791, and is considered the guiding document for the economic principles of the United States. The *Report on Manufactures* was followed by specific reports on banking and credit. The Report was analogous to an economic Declaration of Independence, to be followed by constitutional specifics. It was originally opposed by the then secretary of state, Thomas Jefferson. The disagreement between Hamilton and Jefferson derived from two different visions. Jefferson saw the United States as an agrarian nation where manufacture would be done on large plantations. Hamilton foresaw an urban nation of manufacturing cities. By Jefferson's death in 1825, he had come to accept Hamilton's vision of an industrial America.

The Report was considered a blend of mercantilism as practiced in England and the practices of Jean-Baptiste Colbert of France. It would reject the recent ideas of Adam Smith's free trade and minimal government interference. It would be the foundation of the emerging Federalist Party. Ultimately, Hamilton's ideas would be incorporated in the "American System" of Henry Clay's Whig Party in the 1830s. The young Whig, Abraham Lincoln, would incorporate it into the newly formed Republican Party. Later, in the 1880s, William McKinley would make it the cornerstone of Republican Party platforms for decades to come. Much of Hamilton's vision for the United States has come to pass. In 1790, Hamilton faced a financial mess. The country lacked international and domestic

credit. The currency was worthless, and soldiers paid in script were near rebellion. While free, the country was facing financial collapse.

Hamilton believed that the United States would fail if it did not excel in manufacturing. He reasoned this from his experience as a young military officer under George Washington in the Revolutionary War. The army had suffered from lack of arms, gunpowder, uniforms, iron implements, and ammunition, which nearly cost the States the war. American manufacturing had lacked capacity, and the success of the British blockade had nearly crushed the struggling Continental Army. In the report, Hamilton noted, "The extreme embarrassment of the United States during the late war, from incapacity of supplying themselves, are still matter of keen recollection." After that experience, Hamilton believed that the United States needed to build a strong manufacturing sector if it wanted to remain free. Furthermore, the country lacked a transportation system to supply the army. Hamilton stated, "Those hands, which may be deprived of business by the cessation of commerce, may be occupied in various kinds of manufactures and other internal improvements. If . . . manufactures should . . . take root among us, they will pave the way, still more, to the future grandeur and the glory of America." Hamilton argued that national industries should be supported through protective tariffs, direct subsidies, a national banking system, and a national transportation system. Hamilton refuted Adam Smith's work on the grounds that it was based on an agricultural society.

Hamilton argued for protective tariffs not only to protect infant industries but also to provide a source of revenue for the government. A Congress in need of money to pay off war debts quickly adopted this part of the report. Most opponents were Southerners, such as Jefferson and James Madison, of the Democratic-Republican Party of the time. The South feared that tariffs on imports would cause retaliation affecting their exports of cotton and tobacco. The division would remain and would be the root cause of the Civil War. The Hamilton tariff was to be a moderate one that was of more use in raising money for the government than full protection would have been. The more hotly debated part of Hamilton's plan was direct government subsidies to manufacturers. Most argued for

indirect subsidies such as the building of roads and canals. Even manufacturers preferred a high tariff for protection versus government subsidies, which might lead to political favoritism.

Hamilton was correct in that American industry was starved of cash needed for investment. Banks were almost nonexistent in America except for those serving large planters. England had been the source of capital for America, so banks had failed to fully develop. On Hamilton's recommendation, Congress chartered the First Bank of the United States on February 25, 1791. Hamilton modeled the bank after the Bank of England. The First Bank of the United States was opposed by the Southern states.

Hamilton used the "commerce clause" of the Constitution to justify this expansion of the federal government. The First Bank was a chartered private company with government backing. Stock of \$10 million was sold, with the federal government buying \$2 million of it, which was financed by an excise tax on domestically distilled whiskey. This would ultimately lead to the Whiskey Rebellion. The First Bank did establish order in the newly formed United States. Part of the "bank bill" established a National Mint to replace the more than 30 currencies in circulation. The First Bank allowed New England merchants to establish international credit to promote trade. Furthermore, the First Bank supplied badly needed capital to manufacturers in Pennsylvania, Connecticut, and New York. The bank also served a secondary role as a depository for government accounts. The debate over the bank would lead to the formation of two political parties—the pro-Federalists of Hamilton and the Democratic-Republicans of Jefferson.

The First Bank of the United States was chartered only until 1811, and it continued to be opposed by the Southern states, which saw no benefit from it. The bank's charter was allowed to expire under President Madison, and Congress, by a narrow margin, did not recharter it. Overall, Hamilton's Federalist approach to business would be called "supply-side economics" today. The Federal Reserve today functions similarly to Hamilton's original thinking. Hamilton would have agreed with many government actions to foster manufacturing. Hamilton, however, would not agree with the free trade practices of today.

River Steamer

For all his many accomplishments, Robert Fulton is best known for the development of the commercial steamboat or river steamer. Drawing upon the work of inventor John Fitch, Fulton took Fitch's unwieldy model and turned it into the commercially viable vessel that transformed American travel and trade.

Robert Fulton had lifelong interest in boats and waterways. The early part of his life was spent pursuing a career as an artist, but he abandoned that career to go to Europe to study canal building and invent different types of boats. In 1806, Fulton returned to the United States and devoted himself to the development of a river steamer.

Looking to build upon the ideas of John Fitch, Fulton formed a partnership with prominent New York Founding Father and former ambassador to France Robert Livingston. Aware of a steamboat called the *Experiment* that had made trips on the Delaware River in the early 1790s, Fulton and Livingston sought to take advantage of the Hudson River and the commercial opportunities tied to fast-growing New York City by developing a better steamboat.

Their ultimate production, the *Clermont*, had roots back in experiments relating to the water resistance capacity of various hulls that Fulton began in 1801. Indeed, while in Europe, Fulton was exposed to some of the work being done by the many Europeans who were pursuing similar goals. Putting that knowledge to work, in August 1803, Fulton launched a boat that traveled against the current on the Seine for about a mile and then, turning around, moved with the current

at an even faster speed. While the speed fell well short of the 16 miles per hour that Fulton had envisioned, the trial confirmed Fulton's fundamental ideas about the basic design principles. So pleased was Fulton that he sought to use the demonstration to get support and funding from Napoleon and the French government. But after he was rebuffed, the project lay dormant as the sometimes scattered Fulton turned his attention back to his submarine. When that effort proved unsuccessful, he decided to return to the United States determined to develop a commercially successful steamboat on America waters.

Arriving back in the United States in December of 1806, Fulton focused his attention on building a steamboat that could cruise the Hudson River. He was under some time pressure, as his partner, former ambassador Robert Livingston, had secured a monopoly for steamboat use on the Hudson, but to maintain the monopoly, he had to have a boat in operation by the end of April; otherwise, the monopoly would be lost. Too, an extended delay would mean that the potentially lucrative summer-and-fall travel season would be lost. As April approached, Livingston secured a two-year extension, but in fact, after a few tests in late July, Fulton had a boat ready to be launched on the Hudson River.

Indeed, able to draw upon his European efforts while also being able to adapt some of the existing examples of steam-powered riverboats, Fulton developed a model that became the first economically feasible commercial steamboat. This craft was a side-wheeler paddleboat that had auxiliary sails. The flat-bottomed boat had a square stern and drew only two feet of water. Powered by a coal-fired steam engine brought over from England, the vessel was 146 feet long and 12 feet wide. Not only did it exceed previous efforts in terms of speed and maneuverability, the new boat offered passenger comforts never previously imagined, including sleeping accommodation for lengthy trips.

The boat was originally named the *North River Steamboat*, but in honor of the Livingston family estate on the Hudson, Clermont, the name was changed. The rechristened vessel was launched on August 17, making its first trip up the Hudson River from New York City to Albany. The *Clermont* was an immediate success, and with travelers clamoring, Fulton and Livingston established the North River Steamboat Company,

beginning regular operations between the state's financial center and its capital. While in some quarters Fulton's early efforts were greeted with skepticism, with the boat referred to as "Fulton's folly," not only did it prove to be a commercial bonanza, but within five years, Fulton had boats on six major rivers and the Chesapeake Bay.

In their success in New York, Fulton and Livingston secured exclusive rights to run their steamboats on New York rivers as well as on the lower end of the Mississippi. Fulton recognized that the real need for a service like his was not on the eastern rivers but rather on the western feeders and tributaries, where there were few or no roads. With that in mind, the Company introduced the *New Orleans*. Built in Pittsburgh and launched in 1811 on the Ohio River, the steamer proceeded along until it scraped bottom as it reached Louisville. The incident was a harbinger of problems that the boat would encounter on the western rivers, where sandbars and other natural hazards were commonplace. In addition, while it eventually reached New Orleans, the return trip ended when the *New Orleans* could not buck the current above Natchez. With its creators unable to solve the problem, for its remaining two years on the water, the *New Orleans* simply provided service between Natchez and New Orleans. In the face of these challenges, Fulton and Livingston decided to abandon the western market, refocusing their efforts on the east.

The abandonment of the western routes did not hurt the Company's business. In fact, the number of eastern boats in operation only enhanced Fulton's reputation as an inventor and a businessman. Neither he nor Livingston were able to enjoy their success for long. Livingston died in 1813 after suffering a fatal stroke, while Fulton died in 1815 at the age of 49, succumbing to pneumonia after venturing into the freezing Hudson to rescue a friend.

Rumford Fireplace

American-born Benjamin Thompson invented the Rumford fireplace during the American Revolution. Because he joined the British Army and was later knighted by King George III, the inventor of the Rumford fireplace was also known as Count Rumford. Rumford invented the Rumford fireplace—which became the first modern kitchen range—to improve the quality of London’s polluted air and for the general public to save fuel. He designed the tall, elegant stove as a narrow, shallow construction with a streamlined, rounded, wide-angle throat. This latter area was the space under the damper and above the firebox and was where the fireplace smoke passed through first. Rumford’s curved, repositioned chimney throat funneled the smoke upward and out. With its fluid dynamics, he created a clean-burning fireplace that wasted less heated air by reflecting radiant heat, the most useful heat, away from the fireplace and into the room. It’s a simple fact: a tall fire burns cleaner. Because the Rumford fireplace was tall, it kept the smoke and combustion of flame products hot longer and produced only a small amount of smoke and pollution.

The Rumford fireplace, with its clean, whitewashed plaster firebox, was energy efficient, improved air quality, and became the globally renowned state-of-the-art fireplace by the 1790s. U.S. president Thomas Jefferson had eight of the fireplaces installed in Monticello, his palatial home located in Virginia. Rumford had revolutionized the construction of fireplaces and chimneys and his products were so common, the general public referred to fireplaces as Rumfords. Rumford wrote an essays in 1796 entitled, “Chimney Fireplaces, with Proposals for Improving them to Save Fuel; to Render Dwelling-houses more Comfortable and Salubrious, and Effectually to prevent Chimneys from Smoking,” and in 1798, he wrote another essay to detail his energy-efficient fireplace. Rumford fireplaces swept the country. Chimneys came inside or were incorporated into the exterior walls of houses because it was easier to build them over the shallow fireplaces rather than to slope flues through the wall to an exterior chimney.

The Rumford fireplace was part of the Chicago World’s Columbian Fair exhibit in 1893. It was part of the Massachusetts contribution and the Department of Sanitation and Hygiene’s exhibit officially known as the “Rumford Kitchen.” Besides the Rumford fireplace,

Designed by Benjamin Thompson, Count Rumford, the tall and shallow Rumford fireplace improved fuel efficiency both by its shape and by its use of polished plates, which reflected heat from the firebox into the room. (12/ UIG via Getty Images)

Count Rumford's designs for a baking oven, a double boiler, a pressure cooker, and drip coffee maker were also featured. The Rumford fireplace is even being used to replace decorative fireplaces today, as it remains a fuel-saving, heat-efficient, ecologically correct heat producer in homes throughout the world.

Rush, Benjamin (1746–1813)

Benjamin Rush was a physician, educator, and politician who was also a Founding Father of the United States and a signer of the Declaration of Independence. Writing extensively on the topics of medicine, politics, and social issues for nearly 50 years, Rush was the first American physician to become widely known around the world. He elevated the study of medicine in the United States, and his position as an educator gave him far-reaching influence in the profession. Of particular note are his texts on psychiatry, extensive accounts of the yellow fever epidemics of 1762 and 1793, and his descriptions of cholera infantum and dengue fever.

A firm believer in higher education, he was a founder of Dickinson College in Carlisle, Pennsylvania, and Franklin College (now Franklin and Marshall) in Lancaster. Rush was also one of the first to promote the study of veterinary medicine in North America.

He was born on January 4, 1746, in Byberry Township, Pennsylvania. After his father died in 1751, his mother moved to Philadelphia, where she ran a grocery store. At the age of eight, Rush was sent to live with his uncle, who ensured that Rush received an education. He entered the College of New Jersey (now Princeton University) in 1759, earning a bachelor of arts degree the following year at the age of 14.

Rush returned to Philadelphia, and at his uncle's urging, he apprenticed under John Redman, one of the first physicians at Pennsylvania Hospital and the first president of the Philadelphia College of Physicians. Redman encouraged his protégé to study abroad, so in 1766, Rush left North America to attend the University of Edinburgh, which had one of the preeminent schools of medicine at the time.

After receiving his medical degree in 1768, Rush spent several months training at St. Thomas's Hospital in London. While there, he met Benjamin Franklin, who persuaded him to visit France and partially funded the trip. This enabled him to meet other esteemed physicians and scientists of the day.

In 1769, Rush returned from Europe and started his own medical practice. That same year, he was appointed professor of chemistry in the University of Pennsylvania's medical department. The following year, he published *A Syllabus of a Course of Lectures on Chemistry*, the first American text on the teaching of that subject.

An enthusiastic supporter of the American independence movement, he was elected to the Pennsylvania delegation of the Second Continental Congress in July 1776 and signed the Declaration of Independence on August 2. He married Julia Stockton the same year, and together, they had 13 children. Their son Richard Rush, born in 1797, would serve as a cabinet officer or ambassador under four presidents.

In 1777, Rush was commissioned surgeon general of the Middle Department of the Continental Army, but he became so frustrated with the disorganization and corruption he found in the army's hospitals and his superiors' lack of action to correct it that he resigned after only 10 months.

The causes of disease were not yet known in Rush's time, but the many recommendations that he made to improve care in army hospitals were consistent with hygienic practices today, showing movement toward connecting a lack of sanitation and the spread of disease. In his letters to his superiors, he expressed his despair that more soldiers were dying of sickness in the hospitals than were being killed on the battlefield. He recommended that mildly ill soldiers be kept separate from those with more serious illness, that blankets covering dying soldiers not be reused, and

that overcrowding be eliminated. He suggested bathing, washing hands at least once a day, and using clean cooking utensils and clean clothes.

After resigning his surgeon general post, Rush returned to Philadelphia and resumed his private practice. In 1784, he accepted a position as a surgeon at the Pennsylvania Hospital. In 1786, he founded the Philadelphia Dispensary to provide medical care for the poor, the first such institution in the United States.

It was at the Pennsylvania Hospital that one of his greatest contributions to medical science took place, in the form of the reforms he instituted in the care of the mentally ill. Pennsylvania Hospital had been founded in 1751 to care for mental patients and the poor. While the stated purpose of the hospital was to provide treatment and possibly a cure for mental illness, the harsh conditions there were unlikely to help meet that goal.

Patients were kept in filthy, unheated cells and were frequently chained by their waists or ankles to the wall, their heads shaved. The cells were on the ground floor of the building, where crowds would gather to watch the patients' often odd behavior. A fence was built in front of the windows to curb this activity, but it proved insufficient to keep the crowds away. It was also very easy to commit a patient to the hospital. Relatives, friends, or neighbors could simply sign paperwork to apply for someone's admission. The patient could not appeal the decision.

Rush studied this situation for several years, and in 1789, he addressed the hospital's board of managers, requesting improvements in the patients' quarters. He recommended that the open chamber pots be replaced with closed ones to reduce odors. Cells should be furnished with mattresses and chairs, and patients should be allowed reading material. He also suggested that those who were able to work be allowed to do so.

Rush's opinions were greatly respected, and the board immediately resolved to change existing conditions. He later suggested further reforms surrounding the training and employment of suitable people to care for patients. As basic as these reforms seem today, they were entirely new ideas in the treatment of mental diseases in the United States at the time and paved the way for its mentally ill toward a future of possible improvement and even cure.

Rush's interest in mental diseases is also found in his writings and lectures. To him, the study of the mind was an integral part of the field of medicine, and he recommended its adoption into the medical curriculum. In 1812, he published *Medical Inquiries and Observations upon the Diseases of the Mind*, the first textbook on psychiatry in America. This book and an earlier article titled "Influence of Physical Causes upon the Moral Faculties" were for many decades the only American publications on the subject of mental disease. Of major importance was Rush's belief in the curability of mental disease, which he impressed repeatedly upon both the readers of his texts and his students in lectures.

Despite this forward thinking, however, Rush was still a physician of his time and applied treatments that ranged from ineffective to actively dangerous for his patients. He was an enthusiastic proponent of what was known as "depletion therapy." This involved bloodletting and dosing patients with strong purgative medicines that brought on explosive diarrhea. Rush sometimes drained his patients of 6 to 8 pints of blood over several days (the human body contains about 12 pints). He believed in unitary theory—that all disease came from a single source in the body—and that this source was an overstimulated nervous system that caused, in his words, an "irregular convulsive action of the blood vessels." Depletion theory was meant to bring the body back into balance.

Rush would eventually patent his own purgative, "Dr. Rush's Pills," commonly referred to as "thunder clappers." These contained a mercury compound called calomel, and jalap, the tuberous root of a tropical climbing plant.

In 1793, a severe yellow fever epidemic struck Philadelphia. From August until November of that year, 4,000 to 5,000 residents—approximately 10 percent of the population—died of the illness. Rush used his favorite treatments of bloodletting and purgatives in an attempt at a cure but had few successes. About half of his patients died.

Afterward, a number of his colleagues accused him of excessively applying his therapy. Additionally, his insistence that yellow fever arose from unsanitary conditions upset many of his fellow Philadelphians. Despite this, stories of Rush's devotion to his patients

while other physicians (and many other citizens as well) fled the city made him a hero to many.

In the spring of 1813, Rush fell ill with a fever (most likely typhus) and died five days later. He was eulogized by fellow Founding Fathers Thomas Jefferson and John Adams, among others. In 1837, a group of Rush's former students founded Chicago's Rush Medical College in his honor. In 1965, the American Psychiatric Association placed a bronze plaque at his grave in Philadelphia, designating him the "Father of American Psychiatry."

Primary Document: Excerpt from the Medical Writings of Benjamin Rush (1805)

Benjamin Rush was not only an important Founding Father but a man who wrote and thought deeply about the medical sciences. He is considered the "Father of American Psychiatry," having published the first American textbook on the subject—Medical Inquiries and Observations upon the Diseases of the Mind (1812). In his writings, he broke new ground when he wrote about the effects that the mind can have on the body.

V. The exercises of the faculties of the mind have a wonderful influence in increasing the quantity of human life. They all act by reflection only, after having been previously excited into action by impressions made upon the body. This view, of the reaction of the mind upon the body, accords with the simplicity of other operations in the animal economy. It is thus the brain repays the heart for the blood it conveys to it, by reacting upon its muscular fibres. The influence of the different faculties of the mind is felt in the pulse, in the stomach, and in the liver, and is seen in the face, and other external parts of the body. Those which act most unequivocally in promoting life, are the understanding, the imagination, and the passions. Thinking belongs to the understanding, and is attended with an obvious influence upon the degree and duration of life. Intense study has often rendered the body insensible to the debilitating

effects of cold, and hunger. Men of great and active understandings, who blend with their studies, temperance and exercise, are generally long lived. In support of this assertion, a hundred names might be added to those of Newton and Franklin. Its truth will be more fully established by attending to the state of human life in persons of an opposite intellectual character. The Cretins, a race of idiots in Valais in Switzerland, travellers tell us, are all short lived. Common language justifies the opinion of the stimulus of the understanding upon the brain, hence it is common to say of dull men, that they have scarcely ideas enough to keep themselves awake. The imagination acts with great force upon the body, whether its numerous associations produce pleasure or pain. But the passions pour a constant stream upon the wheels of life. They have been subdivided into emotions and passions properly so called. The former have for their objects present, the latter, future good and evil. All the objects of the passions are accompanied with desire or aversion. To the former belong chiefly, hope, love, ambition, and avarice; to the latter fear, hatred, malice, envy and the like. Joy, anger, and terror, belong to the class of emotions. The passions and emotions have been further divided into stimulating and sedative. Our business at present is to consider their first effect only upon the body. In the original constitution of human nature, we were

made to be stimulated by such passions and emotions only as have moral good for their objects. Man was designed to be always under the influence of hope, love, and joy. By the loss of his innocence, he has subjected himself to the dominion of passions and emotions of a malignant nature; but they possess, in common with such as are good, a stimulus which renders them subservient to the purpose of promoting animal life. It is true, they are like the stimulus of a dislocated bone in their operation upon the body, compared with the action of antagonist muscles stretched over bones, which gently move in their natural sockets. The effects of the good passions and emotions, in promoting health and longevity, have been taken notice of by many writers. They produce a flame, gentle and pleasant, like oil perfumed with frankincense in the lamp of life. There are instances likewise of persons who have derived strength, and long life from the influence of the evil passions and emotions that have been mentioned. Dr. Darwin relates the history of a man, who used to overcome the fatigue induced by travelling, by thinking of a person whom he hated. The debility induced by disease, is often removed by a sudden change in

the temper. This is so common, that even nurses predict a recovery in persons as soon as they become peevish and ill-natured, after having been patient during the worst stage of their sickness. This peevishness acts as a gentle stimulus upon the system in its languid state, and thus turns the scale in favour of life and health. The famous Benjamin Lay of this state, who lived to be eighty years of age, was of a very irascible temper. Old Elwes was a prodigy of avarice, and every court in Europe furnishes instances of men who have attained to extreme old age, who have lived constantly under the dominion of ambition. In the course of a long inquiry, which I instituted some years ago into the state of the body and mind in old people, I did not find a single person above eighty, who had not possessed an active understanding, or active passions. Those different and opposite faculties of the mind, when in excess, happily supply the place of each other. Where they unite their forces, they extinguish the flame of life, before the oil which feeds it is consumed.

Screw-Cutting Lathe

American physicist Henry Augustus Rowland invented the first high-precision screw-cutting lathe. Screws have been in existence for many thousands of years; however, making them wasn't always an easy task. When first invented, screws were often whittled out of wood by hand. This could be done with something like a chisel or a knife and was done with as much precision as one could manage. Even when the first metal screw was created, one would use a file to make threads in it. However, as previously noted, this was a slow and challenging task that wasn't exactly consistent. In 1775, Jesse Ramsden, an English mathematician and instrument maker, created what is currently called the first "modern" screw-cutting lathe—modern in the sense that it involved a leadscrew, slide rest, and gear change mechanism. Ramsden's lathe was revolutionary because it could make 10 screws per minute.

Mass-produced screws continued not to be entirely interchangeable until Henry Rowland perfected the process in the 1880s. In the course of his work on diffraction grating, he found he needed extremely precise screws and had to invent a new process for making them.

Rowland's method has been made obsolete by thread rolling. A modern planetary rotary die can make up to 2,000 screws per minute.

Screws and Screw-Making, with a Chapter on the Milling Machine. n.d. Colchester, UK: Britannia.

Slater, Samuel (1768–1835)

Textile manufacturing was the first major industry in the United States to develop the factory system of production, and Samuel Slater played a significant role in developing the model that many of the earliest American mills followed.

American attempts to move textile manufacturing away from home-based production into a factory setting were hampered by British competition and by the fact that the British closely guarded the technology and expertise used in textile manufacturing. Britain outlawed the exportation of textile-making machinery or plans for such machinery. People known to be experienced in this field were not allowed to emigrate, and there were penalties imposed on foreigners trying to recruit such workers. These regulations, however, were difficult to enforce. Slater was one of the first British-trained textile mill operators to bring his knowledge and experience to the United States.

Slater was born June 7, 1768, in Belper in the region of Derbyshire in England, which was at the center of the developing textile industry. In 1783, he became an apprentice in a spinning mill under Jeremiah Strutt, who was a partner of Richard Arkwright, the inventor who had perfected waterpowered machinery for spinning cotton thread and provided one of the first major steps toward factory production of textiles. Strutt was one of the first industrialists to become wealthy from investments in that industry. Slater served a six-year apprenticeship under Strutt and eventually became a supervisor of machinery and mill construction.

Slater's apprenticeship ended when he was 21 years old, and he decided that there would be greater demand for his skills and expertise in America than in Great Britain. Despite the laws designed to keep people with such knowledge from emigrating, Slater sailed to the United States under an assumed name, listing his occupation as "farm laborer." He guarded his plans so secretly that he did not even inform his mother until he mailed a letter to her just hours before sailing.

When Slater arrived in November 1789, the U.S. textile industry was still primarily based in home or small shop manufacturing. Cotton thread was spun by one home-based worker, and then the thread was taken

to a weaver, who wove it into cloth. Weavers, however, could use more thread than home-based spinners could produce, so if the thread-making process could be sped up, there would be a ready market for the thread. In the United States, Slater first went to work for the New York Manufacturing Company, which was trying to establish textile mills in that state. Slater found the equipment that this firm was using to be inadequate, and he doubted that it had access to the resources needed for a waterpowered mill.

He soon after learned that Moses Brown, a wealthy businessman in Providence, Rhode Island, was trying to find someone who could repair and operate some spinning machinery that had been constructed in the United States in an attempt to duplicate British designs. Brown had recognized that the home production of thread created a bottleneck because spinners could not keep up with the demands of weavers, and he sought to mechanize the spinning process as British mills had. Slater inspected Brown's machinery and saw improvements that could be made. He convinced Brown to allow him to start from scratch and redesign the machinery needed for a thread-spinning mill.

Working with American carpenters and machinists who had no background with the kind of equipment he was building, Slater created a carding machine and a water frame spinning machine based on Arkwright's prototypes. "Carding" is the process of untangling cotton fibers, cleaning them, and forming them into a "sliver" or wispy cord that can be run through a spinning machine. The "water frame" was a spinning machine capable of spinning multiple bobbins or spindles of thread simultaneously, powered by a water-wheel. It is often said that Slater used his knowledge of British spinning machinery and duplicated their designs, but it is more accurate to say that he created new designs based on his experience with British prototypes. Brown was in partnership with William Almy, another Providence businessman, and Slater agreed to set up the machinery for a share of ownership in the mill.

In 1792, Slater built a waterpowered mill in an existing building in Pawtucket, Rhode Island, which was the first cotton-spinning mill in the United States. The machinery was so simple that nine children, ranging from 7 to 12 years old, were hired to operate it under Slater's supervision. Like most of the early

textile mills in America, this factory produced only cotton thread—which was, again, sold or contracted out to weavers who wove cloth in small shops or home-based businesses. A larger mill in a new building was constructed in 1793, and by 1800, over 100 people worked in this mill.

While Brown and Almy needed Slater's expertise and thus had to agree to include him in a partnership, their relationship was strained, and they tended to view Slater as an employee and also as a potential challenger who needed to be kept in check. All funds for supplies and for paying employees had to come through Brown and Almy's mercantile business in Pawtucket, and they were often late in supplying Slater what he needed to keep the mill running efficiently. Almy and Brown tended to view the mill as simply a part of their larger business activities and not as its own separate enterprise.

Eventually, Slater began building his own mill, although for a time, he maintained his connection with Almy and Brown and oversaw production at their mill. In 1798, he founded Samuel Slater and Company with investments from several people to whom he was related by marriage. He built a mill at Rehoboth, Massachusetts—just across the Pawtucket River from the Rhode Island mill owned by Almy, Brown, and Slater. This mill, sometimes known as the White Mill, was the first in Massachusetts to use Slater's adaptations of Richard Arkwright's waterpowered spinning machines.

Embargoes of British imports during the period leading up to the War of 1812 and the war years of 1812 to 1815 caused demand for American textiles to boom, since there was no competition from British cloth. With many fast-flowing streams to provide waterpower, New England quickly became the center of the new industry. But the end of the War of 1812 brought a time of British "dumping" goods on the American market at low prices. This led many mill operators to begin to incorporate weaving into their mills to undercut this British competition instead of sending their thread to outside weavers. Mills that did both spinning and weaving were often referred to as "integrated mills." The final finishing of cloth by dyeing or bleaching, however, continued to be farmed out to other businesses until late in the 19th century.

In Slater's earliest mills, children did most of the work tending the spinning machines under the oversight of a few adult male supervisors. Men also worked in the mills as mechanics maintaining the machinery and at times building the equipment, since most mills had machine shops for such purposes. Families were recruited to move to the towns surrounding these mills, but at first, Slater sought to keep the fathers in these families involved in traditional work such as farming. He wanted to preserve the traditional family structure, with the father as the chief authority in the home and the one who made the economic decisions for the family. Men might work as laborers on a farm operated by the mill, or they might work individual plots of the company's land on their own as sharecroppers.

Over time, however, opportunities to keep adult males occupied in work outside the mills decreased, and so entire families often came to work in them, especially after power looms were added for weaving fabric. The towns that grew up around Slater's mills tended to maintain the appearance of an idealized New England village of the colonial era; the kinds of large factory buildings and dormitories for workers that characterized Lowell, Massachusetts, and the other mills operated by the "Boston Associates" were slow to appear around Slater's mills. Workers worked long hours for fairly low wages in these mills, but economic historians generally believe that the conditions and pay were fair for the times in comparison to the few options that employees might find elsewhere.

Over his career, Slater played a part in developing many mills in the three-state region of Connecticut, Massachusetts, and Rhode Island. In 1808, there were only 15 power cotton mills in the United States, and Slater owned or was co-owner of eight of these. By 1828, he had been partners in 13 different mill enterprises. Slater trained three of his sons in the milling business, but they did not take significant roles in management until the firm of Samuel Slater and Sons was formed in 1828. They continued the business after their father died.

By the time of Samuel Slater's death on April 21, 1835, the New England textile industry was second in size only to Great Britain's; textile manufacturing was one of the major economic activities in New England and employed thousands of workers. President Andrew

Jackson visited Slater in New England in 1833 and pronounced him “the father of American manufacturers.” Slater’s original mill in Pawtucket is maintained today as a museum and historic site.

Steam Engine

The steam engine was a central invention of the 19th-century Industrial Revolution. Steam power moved boats, trains, water pumps, and much more. A steam engine uses steam as the working fluid to produce mechanical work. Unlike gasoline engines, steam engines are external combustion engines because the working fluid (the steam) is separate from the combustion (the fire that heats the water to make the steam).

Samuel Morey was an early pioneer of internal combustion engines, but he first worked on steam engines, inventing a steam-powered boat in the 1790s. During his stint as an inventor, he was granted over 50 patents for work involving-steam powered boats and engines that used turpentine vapor, among other things.

The earliest recorded steam engine was built by Hero of Alexandria in the 1st century AD. Hero named his machine the “aeolipile” or “Hero’s engine.” Hero’s engine was a steam turbine that consisted of a rotating surface, like a sphere, that was heated with some external source and produced rotation about its axis. Although it was the first recorded steam engine, it saw little to no practical use. One of the first commercially recognized, patented inventions came in 1698 by way of a steam-powered water pump. It was invented by Thomas Savery and was used in coal mining to pump out mines flooded with water.

At their most basic, steam engines are composed of two parts: the boiler, which generates the steam; and the motor unit, which converts the steam into power. While steam engines for boats and locomotives had these two parts in close proximity to each other, stationary steam engines could have the two parts in separate, fixed buildings. Reciprocating steam motors use cylinders, pistons, connecting rods, and flywheels. This type of engine was widely used for most of the 19th century. Some steam engines have condensers to control exhaust while others have pump injectors to move water into the boiler during engine operation. In the 19th century, almost all of these steam technologies were driven by coal, increasing the demand for coal mines and coal miners. Coal boxes often had a chain or screw-stoking system that moved the coal from the coal bin to the engine’s firebox. Some steam engines, notably on early locomotives, required a worker to shove coal manually into the firebox.

In 1712, Englishman Thomas Newcomen invented the first piston-driven steam engine. Scotsman James Watt patented a 10-horsepower steam motor that utilized a partial vacuum. By the early 1800s, steam engines were powering factory machines, pumping stations, railway locomotives, steamboats, and some road vehicles and submersible technology. Steam tractors and steam combines appeared on American farms in the 1840s. Though little remembered, the Stanley Motor Carriage Company manufactured a steam-powered automobile between 1902 and 1924.

American factories were steam powered in the 1800s. Textile factories featured both steam-powered “spinning mules,” which spun cotton into thread or yarn, and power looms, which mechanized the weaving process. While such technological innovations are often celebrated, mechanizing the textile industry first reduced wages and then caused wide-scale unemployment among skilled weavers. Also, the mechanized nature of steam-powered factories meant that skilled workers could be replaced with low-waged, unskilled workers. Nineteenth-century textile workers, many of them young women and children, worked 12-hour days, six days a week in factories that were often unsafe and uncomfortable.

The now-iconic steam railway locomotive was first invented in 1784 by Scotsman William Murdoch.

The first American-built steam locomotive to operate on a public railroad was the *Tom Thumb* locomotive. In 1830, inventor and philanthropist Peter Cooper designed and built the small steam engine. The *Tom Thumb* came to public notice when it was featured in a race against a horse. At first, the engine made a good showing in the race, easily pulling away from its equine competition, but the engine threw a pulley belt, lost power, and lost the race. Nonetheless, *Tom Thumb*'s performance made people understand that steam locomotives were the coming thing. By mid-century, steam locomotives ruled the American transportation revolution. They also became crucial in the prosecution of the Civil War. The Union simply had more miles of railroad, more steam locomotives, and better facilities for making new engines and repairing old ones than did the Confederacy.

Steam turbines also played a significant role in the Industrial Revolution. Steam engines were designed to be used as turbines (rotary-powered, energy-producing machines) in the late 19th century. Steam turbines proved so successful that they gradually replaced piston-driven systems. Steam turbines still produce almost 90 percent of the electrical power in the United States and were widely used to propel large ships for most of the 20th century. Modern steam turbines are powered with solar energy, geothermal energy, internal combustion engines, or hydroelectric energy. While coal is also still used to power electrical plants, this type of energy production fell out of favor by the end of the 20th century because it is a “dirty” and unsustainable energy production system.

While steam engines powered the 19th-century Industrial Revolution with its attendant positive and negative realities, the gasoline-powered, internal combustion engine largely replaced steam by the end of the century. Some countries, like Malaysia, still use steam engines to run locomotives. In Sweden, the company Energiprojekt AB is working on a modern five-cylinder steam engine that uses superheated steam. The company hopes to create a clean engine that can replace gasoline-powered, internal combustion engines.

Steam Tractor

The steam tractor is a piece of machinery that was used in place of a horse-drawn plow to efficiently prep an area of land for use in farming in the late 19th and early 20th centuries.

Originally developed in the early 19th century, the steam tractor was an innovative piece of technology that, during its era, revolutionized the agricultural industry. There were two distinct areas that began to develop this new form of technology: North America and Great Britain. This particular piece of equipment was originally a simple steam engine placed on skids or wheels and transported to a specific work area by a team of horses. Further development of the steam tractor allowed the steam engine to power its own movement using a traction drive, which gave the equipment more independent mobility and allowed it to be moved without the use of horses. These driving mechanisms can be separated into three categories: shaft, chain, and open pinion. They allowed the steam engine to be an extremely viable option for agricultural use around the world.

Steam tractors in the early 19th century were developed for two main purposes: to plow fields and thresh grain. They were extremely expensive at first, so farmers banded together to rent them to complete large jobs quickly. This could not have been possible had they used only horses.

The steam tractor was an important innovation that led to modern farming. Without it, it would have been much more difficult in the last two centuries to grow enough food to support the world's growing

population. The steam tractor was an early form of today's plowing equipment; it was slowly phased out of operation by the 1920s. The much more efficient internal combustion engine replaced the steam engine, emerging just after World War I.

Steamboat

A steamboat is a waterborne vessel propelled by steam power that usually drives paddle wheels. Steamboats were the means by which the United States grew from its infancy into a prosperous, expanding nation in the 1800s before the coming of the steam locomotive.

With America's vast system of interconnected rivers and waterways, steamboats linked isolated communities with the larger world, cutting huge distances and travel time to a fraction of what they had been. From the early 1800s to the 1870s, steamboats turned waterways such as the Mississippi and Ohio Rivers into the superhighways of their day, churning the waters up- and downstream like a latter-day rush hour. Mark Twain made riverboat pilots into larger-than-life figures in American culture, just as riverboat gamblers entered their own mythology. Both species flourished in the era of the steamboat.

Steamboats are not to be confused with "steamships" (often called "steamers"). After the invention of river steamboats in the early 1800s, steam power

began to be used for larger, oceangoing vessels. Steamships, though also powered by a steam-generated system utilizing paddle wheels or propellers, are heavier vessels that can travel the major seas and oceans of the world. Steamboats, often called "riverboats," do not require deep water and usually ply rivers and lakes.

Before the heyday of steamboats in America, there were the flatboats. Moving produce to markets and occasionally carrying passengers, flatboats were an important form of transportation in America even before it became a nation. The colonies, still fighting their War of Independence, took note in 1781 when Pennsylvania farmer Jacob Yoder plied the Monongahela River in a flatboat to carry flour. In 1782, Yoder became the first recorded person to successfully navigate a flatboat from Brownsville, Pennsylvania, to New Orleans, Louisiana, demonstrating how waterways could be used to reach distant locales.

Flatboats were rectangular, flat-bottomed, tub-like boats that were relatively easy and inexpensive to make. Though built in various sizes and configurations depending on the load and distance to be traveled, they were often about 4 feet wide and 16 feet long with no covering, or just a simple shelter with a cooking area. They were guided by a flatboatman with a paddle attached to a long pole. With their long, narrow shape and shallow draft, flatboats could navigate America's ample supply of rivers and even creeks. But flatboats had a huge drawback: they could only go one way. They could usually only travel by being carried with the current downstream, literally able only to "go with the flow." When flatboatmen reached their destination, they dismantled their boat, sold it for lumber, and would often walk home.

Still, with the abundance of small waterways in North America, during the first half of the 1800s, flatboats became one of the most important modes of shipping in the United States. Once the flatboats followed the streams of America's heartland to join the Mississippi, the current could propel them to New Orleans, where their products could be shipped overseas. Most often, their cargo included corn, flour, fruit, furs, pork, vegetables, and whiskey. Though flatboats were slow, uncomfortable, and easily attacked by marauders, passengers could be carried alongside cargo, usually having tent-like coverings for shelter.

While flatboats continued to be an important means of transport on smaller waterways as the 1800s progressed, steamboats started to appear on western rivers in 1807, much to the delight of both shippers and passengers, who found them far more efficient, faster, and boasting one important advantage: they could also travel *upstream*.

The steamboat age began soon after Scottish inventor James Watt (1736–1819) patented his version of the steam engine in 1769. John Fitch (1743–1798) was granted a U.S. patent for a steamboat in 1791 after making the first successful trial of his 45-foot steamboat on the Delaware River in 1787. Fitch would go on to build larger vessels that carried passengers and freight to and from Philadelphia, utilizing various combinations of propulsion, including paddle wheels and screw propellers. However, due to construction and operating costs, Fitch was unable to make his venture an economic success.

After the death of John Fitch, American engineer and inventor Robert Fulton (1765–1815) built his first steamboat. It was Fulton who was to become known as the father of steam navigation, after being originally mocked by naysayers as the perpetrator of “Fulton’s folly.”

Fulton had married into New York’s wealthy Livingston family. With their support, he built the first commercial steam riverboat, the *North River Steamboat* (later known as the *Clermont*, named for the Livingston estate in upstate New York). On August 7, 1807, Fulton’s *Clermont* traveled 150 miles up the Hudson River from New York City to the state capital of Albany, steaming into history. By transporting passengers on the *Clermont*’s round trip to great acclaim, Fulton is generally credited with developing the first commercially successful steamboat.

Fulton’s destiny was joined with that of waterborne shipping in the United States. He was appointed a member of the Erie Canal Commission, where he served until his death. He and his partner Robert Livingston worked in 1811 to design the steamboat *New Orleans* to put it into service as a passenger and freight boat along the Mississippi River. To do so, they joined with another partner, also from a distinguished New York family, Nicholas Isaac Roosevelt (1767–1854).

Their plan was to build the *New Orleans* specially designed to make the long trip from Pittsburgh, Pennsylvania, down the Ohio River. The journey would include stops at Wheeling, Virginia, and Cincinnati, Ohio. The boat would have to pass through the Falls of the Ohio at Louisville, Kentucky; continue to Cairo, Illinois; and meet the juncture with the Mississippi River. It would then pass St. Louis, Missouri; Memphis, Tennessee; and Natchez, Mississippi, on its way to the town of New Orleans, Louisiana, on the coast of the Gulf of Mexico. Roosevelt not only introduced his partners to the vertical paddle wheel for steamboats but would also navigate the first voyage on their untried vessel himself, accompanied by his pregnant wife, Lydia Latrobe Roosevelt (1791–1878).

The steamboat *New Orleans* was the first on the western waters. She set out on her journey downriver from Pittsburgh on August 26, 1811. It is important to note that the voyage of the *New Orleans* took place only eight years after the United States had acquired the vast, unknown Louisiana Territory in 1803. The rivers and lands surrounding the Roosevelts were not yet well settled, mapped, or protected.

Not only were those perils daunting enough, but passing Missouri, the Roosevelts would encounter one of the major natural disasters in American history: the 1811–1812 New Madrid Earthquake, which began on December 15, 1811. In a calamity that is expected only every 350 to 400 years, some streams ran backward, the banks of the Ohio and Mississippi Rivers crumbled, islands appeared where there had been none, and others disappeared overnight—one of which was once to serve as a tie-up point for the steamboat. The air filled with sulfur, the sun was blacked out, downed trees and other debris filled the river, and terrified animals flocked to stay near equally terrified humans. But the *New Orleans* was built and balanced well enough that she was able to continue her journey, even though, as Lydia wrote, “I lived in a constant fright, unable to sleep or sew or read.” Finally, as the steamboat neared Natchez, Mississippi, in late December, the earthquake began to abate, and the Roosevelts were greeted by cheering crowds. Continuing her journey, the steamboat reached her namesake city of New Orleans on January 10, 1812.

The crowning achievement of the steamboat *New Orleans* was to reverse course and successfully sail back upstream on the Mississippi against the current. In that one move, she changed the course of transportation in America.

By 1814, Robert Fulton and his partners were offering regular steamboat and freight service between New Orleans and Natchez. Their boats traveled at the rates of eight miles per hour downstream and three miles per hour upstream.

Steamboat design continued to improve. Between 1814 and 1834, annual steamboat arrivals at the port of New Orleans increased from 20 to 1,200.

In the western United States, riverboats transported cargoes of cotton and sugar as well as passengers. In the East, steamboats contributed significantly to the economy by transporting agricultural products and raw materials to fuel the Industrial Revolution.

Larger than canal boats or flatboats, steamboats had a steam engine that turned a paddle wheel, which was usually at the back of the vessel. Some had two paddle wheels, one on each side of the steamboat—which could then reach greater speeds. The paddle wheels propelled the steamboats both up- and downriver and allowed them to travel much faster than the flatboats they had replaced. Steamboats carried more cargo, had room for paying passengers, and did not have to be dismantled after the trip.

Steamboats also had a shallow draft and efficient flat-bottomed construction that allowed them to navigate rivers that were only 10 feet deep. Though many of America's rivers and streams are wide, they are often relatively shallow. Steamboats frequently influenced shoreline patterns; farmers would grow crops along the river because it was easy to get them to market. Small towns and growing cities emerged near rapids and forks in the rivers.

Because steamboats were stable and comfortable to ride on, luxury accommodations were built on some, enticing the wealthy to board riverboats and bringing greater financial resources to America's new frontiers.

Providing previously unseen levels of comfort and speed, steamboats of the 1800s captured the imagination of the American people. Even poorer people could secure passage if they didn't mind sleeping on freight decks, using bales of cotton or sacks of grain for beds.

The finer steamboats offered luxurious onboard accommodations for those who could afford them. Grand salons under gilded ceilings ran the length of some boats, usually about 300 feet. Furnishings were elegant, with their heavy wood reflected by mirror-lined walls. Private cabins on the upper decks were available for the wealthy, along with fine food and drink. While on board, games of chance among passengers were not unknown, giving rise to the era of the riverboat gamblers.

There were also races between rival steamboat captains. Some wished to provide entertainment for their passengers or to secure bragging rights on the river. For others, it was strictly business as they tried to beat other boats to the next landing to pick up goods or paying passengers before anyone else. Since steamboat races often resulted in accidents, boiler explosions, or fires, federal safety legislation in 1838 and 1852 sought to put a stop to them, though some racing continued well after the Civil War.

Ironically, one aspect of the steamboat era is the one image of it most recognizable today, yet it is technically incorrect. "Showboats" brought rousing entertainment to isolated port towns, but they were not steamboats. Showboats were essentially barges that had to be pushed by a small tug, since the stage and auditorium took up space amidships where the steam engine would normally need to be placed.

As the importance of steamboats rose astronomically, the General Survey Act was passed by Congress in 1824 to authorize surveys made of transportation routes "of national importance, in a commercial or military point of view, or necessary for the transportation of public mail." The 1824 Navigation Act appropriated \$75,000 (about \$1,650,000 in 2015 dollars) to improve navigation on the Ohio and Mississippi rivers. The 1826 Rivers and Harbors Act authorized additional surveys and maritime construction projects.

By the 1850s, steamboats dominated river transportation. In the western United States, there had only been 17 steamboats plying the rivers in 1817. By 1855, there were over 700.

Steamboats went to war between 1861 and 1865. Along with the ability to carry more goods and passengers, the increased power of a steam engine allowed the development of armored warships. The *Monitor* and the *Merrimack*, steam-powered ironclad vessels,

saw action during the Civil War when they fought off Hampton Roads, Virginia, in 1862.

The speed and maneuverability of steamboats outclassed older sailing ships by far. Federal steamboats proved vital in securing the Mississippi River and other major waterways, influencing the course of the war and the Union's victory.

In peacetime, along with their luxury and relative safety, there were also dangers to traveling by steamboat that could not be denied. With all-wood boats powered by the blazing fires that generated steam, there were boiler explosions and catastrophic fires. By 1848, steamboat explosions in the United States had cost the lives of almost 2,000 people and untold numbers of animals on board, destroying over 200 boats. Obstacles and snags such as fallen trees in the water caused some riverboats to sink. Sandbars and shifting channels, occurring due to changes in a river's path, made waterways such as the Mississippi virtual obstacle courses. During his American tour of 1842, British author Charles Dickens described the Mississippi as "an enormous ditch, sometimes two or three miles wide, running liquid mud . . . its strong and frothy current choked and obstructed everywhere by huge logs and forest trees."

When snowmelt from northern streams brought high water every spring, shorelines were scoured and eroded, dragging land, buildings, and huge trees into rivers like the Ohio and Mississippi. In especially big floods, the curving lower Mississippi was disastrously prone to cutting across one of its meanders to create a new channel. Steamboat pilots, such as those described by Mark Twain, had to rely on experience, word of mouth, and sometimes just their instincts to guide their way through treacherous, shifting channels. One narrow stretch of the Ohio River was nicknamed "the

Graveyard" because of the number of wrecks that occurred in the snags of its channel when riverboat pilots miscalculated.

The most appalling steamboat catastrophe, which remains the worst maritime disaster in U.S. history, took place on April 27, 1865. In the flood-swollen Mississippi, the steamboat *Sultana* exploded and sank while transporting former Union Army prisoners of war back home just after the Civil War ended. By dark of night, the all-wood boat was quickly engulfed in flames, and passengers who were not scalded or burned to death awoke to find themselves drowning in the rushing currents of the river. At least 1,800 people, including about 40 women, were killed.

Despite the dangers, America's steamboat era flourished until railroads adopted steam technology to power locomotives, with rail travel beginning to overtake it by the 1870s. Just as steamboats supplanted the canal era, railroads replaced steamboats as the major transporter of both goods and passengers. But during their heyday, steamboats plied the nation's rivers as if on a watery superhighway.

Primary Document: Newspaper Announcement of Robert Fulton's Steamboat (1807) and Charles Dickens's Account of His Ride on an American Steamboat (1842)

The following are documents describing steamboats in 19th-century America. The first is a newspaper announcement of the sailing of Robert Fulton's early steamboat on the Hudson River in New York in 1807.

The second is an excerpt from American Notes by British novelist Charles Dickens, who visited the United States in 1842. In this excerpt, Dickens writes about his experience on an American steamboat.

Fulton's Steamboat

"Mr. Fulton's ingenious Steam Boat, invented with a view to the navigation of the Mississippi from New-Orleans upwards, sails to-day from the North River, near the State Prison, to Albany. The velocity [sic] of the Steam Boat is calculated at four miles a hour; it is said that it will make a progress of two against the current of the Mississippi; and if so it will certainly be a very valuable acquisition to the commerce of the Western States."

Source: [New York] *American Citizen*, August 17, 1807.

Dickens's Account from American Notes

Occasionally we stop for a few minutes, maybe to take in wood, maybe for passengers, at some small town or village (I ought to say city, every place is a city here); but the banks are for the most part deep solitudes, overgrown with trees, which, hereabouts,

are already in leaf and very green. For miles, and miles, and miles, these solitudes are unbroken by any sign of human life or trace of human footstep; nor is anything seen to move about them but the blue jay, whose colour is so bright, and yet so delicate, that it looks like a flying flower.

Through such a scene as this the unwieldy machine takes its hoarse sullen way: venting, at every revolution of the paddles, a loud high-pressure blast; enough, one would think, to waken up the host of Indians who lie buried in a great mound yonder. . . . The very river, as though it shared one's feelings of compassion for the extinct tribes who lived so pleasantly here, in their blessed ignorance of white existence, hundreds of years ago, steals out of its way to ripple near this mound: and there are few places where the Ohio sparkles more brightly than in the Big Grave Creek.

Submarine

While best known for the development of the commercial steamboat, Robert Fulton was also instrumental in the development of the submarine, which, in an admittedly different form, remains an important component of every major navy in the world.

As a young man during the American Revolution, Fulton worked in a gunsmith shop, where he discovered the power of gunpowder. That interest, coupled with his longtime interest in all things nautical, led him to undertake the development of the torpedo, an underwater weapon similar to a modern water mine. That work, in turn, led to the exploration of an underwater "diving boat," a submarine, that could serve as the transport for the explosive torpedo.

While he was known to claim originality, especially as he sought funding, it is clear that Fulton's idea and plan for the submarine were drawn at least in part from the recognized earlier work of David Bushnell, who had built a hand-cranked version during the American Revolution. While Bushnell's effort, in practical terms, was unsuccessful, it did plant the idea

of such a vessel in people's minds. At the same time, while building upon Bushnell's practical efforts, Fulton's approach to funding and constructing the submarine was distinctive, based in the belief that it could change the face of international warfare and trade. For Fulton, a central part of the rationale for both the torpedo and the submarine was their ability to allow a smaller nation or force to survive—indeed, to compete—against the larger, more expensive warships of the world's leading nations. In fact, his concerns were as much about the ability of smaller nations to engage in free trade—another subject of longtime interest and that Fulton felt was difficult given the nautical advantages of the large nations in naval warfare.

With a basic concept in mind, Fulton sought funding to make it a reality. He made his first foray in December 1797, submitting a proposal to the French Directory in Paris. He framed the idea as a weapon that could be of great value in their ongoing war with Great Britain and proposed a financing plan in which he would receive a payment for the initial construction and then additional amounts based on the number of guns on the boats that were destroyed. He also offered the French government another option: for a flat fee,

he would direct the construction by the government of a fleet of submarines. But the French rejected the idea. While many dismissed it as impractical, even more saw it as unseemly, a brand of sneaky warfare unfit for gentlemen warriors.

Undaunted, Fulton built a model and went directly to Napoleon. At his urging, in the latter part of 1798, a committee appointed by the government's Marine Ministry studied the plan and issued a positive report that urged the government to allow Fulton to proceed. However, the recommendation was met with silence and, although Fulton railed against the government's inaction, nothing happened. Despite his frustration, Fulton could not abandon the idea of a submarine, and in 1800, he built the *Nautilus* with no governmental support. The craft was cigar-shaped, 20 feet long and 5 feet in diameter. It was driven by a hand-cranked propeller when it was underwater but was propelled by a kite-like sail when traveling on the surface. This combination made it the first submersible vessel to have different types of "engines" for surface maneuvers and submerged travel. No less significant was the fact that the *Nautilus* carried flasks of compressed air that made it possible for its two-man crew to stay underwater for five hours. In successful tests conducted in France, the submarine, carrying a two-man crew, descended to a depth of 25 feet.

Fulton offered his first demonstration of the vessel to a French delegation on the Seine in June 1800. It appeared to be well received, and there is some evidence that the government encouraged his further efforts, for Fulton began to undertake tests in preparation for actually attacking the British. He spent the fall of 1800 stalking the British, but for a variety of reasons, including the probable British awareness of his presence, there was no opportunity for engagement. Nonetheless, his efforts impressed the French, and in early February 1801, they entered into a contract with Fulton that covered the operating costs of the *Nautilus* as well as compensation based on the British ships it would destroy. Fulton also was given access to the naval base at Brest as a base of operations. Accepting the contract, Fulton prepared to take on the British Navy.

The next stage of his saga was a disaster. After bringing the *Nautilus* to Brest and undertaking a new

set of tests, Fulton seems to have abandoned the vessel. Concerned about its speed and maneuverability, he turned instead to longboats as the means to deliver torpedoes to British ships waiting in the harbor. But that did not work. In September, Fulton wrote the French and, while admitting his failure, argued that with more time to work on the torpedoes, coupled with some larger French-built submarines, he could wreak havoc by sneaking into English harbors, where he would release torpedoes. By now, the French had had enough, and when Fulton sank the *Nautilus* to prevent anyone from copying it, their government informed him that they had no further interest in his efforts.

Fulton did make one attempt to interest the British in his submarine, but they deemed it impractical as well as too expensive, although after a number of twists and turns, they did make a deal with him for torpedoes, a venture that proved financially lucrative.

In the end, Fulton abandoned his submarine effort, but not before meeting the U.S. ambassador to France, Robert Livingston, with whom he would partner when he returned to the United States in 1806. To Fulton's surprise, his return was greeted with great fanfare after news of the successful submarine launch became public. That adulation provided a successful launch for his next venture—the steamboat.

Suspension Bridge

A suspension bridge is a type of bridge where the deck is supported by vertical suspenders and suspension cables. Suspension cables are connected to the towers and anchored at each end of the bridge.

In the earliest phases of this type of bridge, simple suspension bridges were made with ropes, animal

The Golden Gate Bridge is perhaps the most famous suspension bridge in the world. The load-bearing deck is suspended from cables, making this and other suspension bridges more flexible and more tolerant of wind and earthquakes than rigid bridges. (Corel)

skins, or wood. A Tibetan saint and bridge builder Thangtong Gyalpo built 58 suspension bridges around Tibet and Bhutan (later ones were built with iron chains) in the 15th century. One of those bridges survived until 2004.

James Finley, a land-owning judge in Pennsylvania, designed the first modern iron chain suspension bridge. The 70-foot bridge was built at Jacob's Creek in Westmoreland County, Pennsylvania, in 1801. He later received a patent for his work. In the United Kingdom, one of the oldest suspension bridges that is still in use is the Union Bridge (449 feet in total length); it was built with wrought iron in 1820. Saint-Antoine Bridge (two 120-foot spans) in Geneva was the first permanent wire cable bridge, built by Guillaume Henri Dufour in 1823.

A French engineer named Louis Vicat developed the air-spinning process for the wire cables in 1830. John

Roebing, a contemporary German-born American engineer, perfected the process at the place of building—instead of transporting prefabricated cables. He designed and built the first modern suspension bridge over the Monongahela River at Pittsburgh in 1845 using his cable-spinning process. He had completed the design and construction of many other suspension bridges, including the John A. Roebling Suspension Bridge (with a main span of 1,057 feet) over the Ohio River. He was appointed as the chief engineer for the design and construction of the Brooklyn Bridge (with a main span of 1,595.5 feet) in 1867. However, he died from an accident before he could finish his work. His son, Washington Roebling, completed the project by 1883. Another major development of that time was the use of pneumatic caissons for the bridge foundation. Washington Roebling learned the technique from French engineers and applied his knowledge to the Brooklyn Bridge's construction.

Many suspension bridges with much larger spans have been built over the years around the globe. The Akashi Kaikyo bridge (with a main span of 6,532 feet) in Japan has been the world's longest suspension bridge since it was built in 1998. Five out of top 10 longest suspension bridges are currently located in China. The two longest suspension bridges in the United States are the Verrazano-Narrows (with a main span of 4,260 feet) and the Golden Gate (with a main span of 4,200 feet); they are currently ranked 12th and 13th in the world. Many of the newest suspension bridges (with main spans ranging from 1,765 feet to 5,600 feet) are currently being built in China.

The main forces in a suspension bridge are tension in the cables and compression in the towers. The slender towers are designed to carry compression loads and are stabilized by the suspension cables. The load from the bridge deck is transferred by the cables to the towers and then to the tower foundation. The advantages of this type of bridge are that they can be built over spaces where conventional bridges cannot be. For example, it does not require access from below during construction. It is also considered more earthquake proof than other types. Suspension bridges are also more economical, since less building material is required for them compared to other types of bridges.

Early suspension bridges with chain-link cables were susceptible to failure if one of the links broke. Modern bridges use cables made of a bundles of high-strength steel strands that maintain structural integrity even with the failure of a few of the strands. A major drawback of suspension bridges was observed in the Tacoma Narrows Bridge when it swayed wildly in wind (it was nicknamed "Galloping Gertie") and finally collapsed under 40-mile-per-hour winds in 1940. Scientists and engineers studied the failure carefully and rectified the flaw in the future design of suspension bridges by increasing the stiffness of the bridge deck significantly using a trussed deck system, making it aerodynamically stable.

Swivel Chair

A swivel or revolving chair is one with a single central leg that allows the seat to rotate 360 degrees clockwise or counterclockwise. Thomas Jefferson is credited for having invented the first one in 1775. He used his unique revolving Windsor chair in Philadelphia while writing the Declaration of Independence in 1776.

Jefferson bought an English-style Windsor chair from either Francis Trumble or Philadelphia cabinet-maker Benjamin Randolph and modified it to incorporate top and bottom parts connected by a central iron spindle, enabling the top half (the seat) to swivel on casters of the type used in rope-hung windows. The chair was made of poplar, mahogany, maple, oak, and hickory. The chair was first used with a Windsor bench and later with a sofa believed to have been made by Thomas Burling.

The comb-back chair, so named because of a resemblance of the crest rail to a hair comb, was unique for its remarkable revolving mechanism, which was specified to an unidentified craftsman by Jefferson. The chair had two seats and rotated on "a central iron spindle and on rollers made of window sash pulleys set in a groove between the two seats." It had volute-carved ears at the ends of the crest rail and knuckle handholds on the arms. It had 11 spindles rather than the usual 9 forming the back. The seat was round rather than the customary *D* shape, with a pommel and a "dished out" seat.

Over the years, the chair was vastly modified in the joinery at Jefferson's Virginia plantation at Monticello. A new base with bamboo-turned legs made either in the joinery or taken from another chair replaced the original baluster-turned legs. The writing paddle was most likely added in 1791 when Jefferson

switched the Windsor couch with the sofa. Jefferson gave the chair to his daughter Martha Jefferson Randolph, who gifted it to J. R. Kane and who, in turn, gifted it to the American Philosophical Society (APS) in Philadelphia on April 20, 1838, citing the chair's history. Jefferson had served as president of the APS between 1797 and 1815.

Jefferson also designed an integrated office-cum-bedroom in his home at Monticello that fit his style of working and anticipated several features that have become fixtures in modern offices. Among the innovations were early "ergonomic" seating (a swivel chair and hassock), task lighting (candles on the arms of the chair), a database (a lazy Susan bookstand that allowed Jefferson to access four books at once), and a personal copying machine (a pantograph on the table in front of the chair).

Modern-day office chairs have swiveling capacity, but they also have wheels, reclining functions, and gas lifts to adjust the height of their seats. Nonetheless, the basic principles of the swivel chair as designed by Jefferson remain the same.

Thompson, Benjamin (Count Rumford) (1753–1814)

Sir Benjamin Thompson, known later in his life as Count Rumford, was an American-British scientist and inventor. He improved a number of inventions and made significant discoveries in thermodynamics.

Born in Woburn, Massachusetts, in 1753, Benjamin Thompson demonstrated his intelligence early in life. As a teenager, he was apprenticed to a local merchant. He began to conduct scientific experiments but seemed destined to become a local merchant. In 1772, he married a rich widow and moved to her estate in New Hampshire. There, he enlisted in the colonial militia. In 1776, he abandoned his family to join the British Army at Boston. He was put to work at the Colonial Office, where he researched the explosive force of gunpowder. His experiments won him a place in the Royal Society.

After the Revolution and the disbanding of many British military units, Thompson toured Europe in 1783. The elector of Bavaria was impressed with the young scientist and offered him a position. Thompson sought King George III's permission and received it and a knighthood in 1784. In 1785, Thompson moved to Munich to assume his duties.

Thompson energetically pursued a number of reforms. He rounded up Munich's beggars and introduced free schools for poor children. He raised the military's morale and performance. He introduced the potato, dramatically improving Bavaria's nutrition. Obsessed with the economical preparation of food, Thompson conducted many experiments. As a result of these experiments, he inadvertently invented sous-vide cooking. Despising alcohol, he invented an early coffee percolator to encourage Bavarian soldiers to drink coffee instead of beer.

Thompson continued basic research while pursuing these practical ends. He conducted many experiments on the nature of heat. He invented carefully calibrated instruments to measure heat and light. He devised a standard candle to measure them, leading to the modern unit of the candela. He was made a count of the Holy Roman Empire for his services, and he chose the name Count Rumford after the estate where he'd lived with his wife in New Hampshire.

In 1795, Rumford returned to England as the government of Bavaria collapsed during an Austrian invasion. There, he continued to publish; his work on heat would later underpin the discovery of the law of conservation of energy. In 1796, he devised the Rumford fireplace, a simple alteration to existing fireplaces that

created a narrow passage at the mouth of the chimney. This prevented air turbulence and allowed smoke to rapidly leave the fireplace, improving the lives of countless people. Generations had dealt with smoky rooms for centuries. He also invented an improved industrial furnace, making it easier to produce large quantities of quicklime from crushed limestone. The quicklime could be used for many purposes, including the manufacture of construction plaster, concrete, steel, and explosives.

The Society for Bettering the Condition of the Poor approached Rumford for advice, based on his work in Bavaria. Rumford quickly spun a grandiose scheme out of a small workshop, and his early attempts to research the best way of improving the lives of London's poor developed into the Royal Institution, a scientific workshop associated with the Royal Society. Rumford clashed with the Royal Institution's management constantly; he was accustomed to giving orders with the authority of a king behind them. In 1802, angered by his colleagues and flattered by an invitation from Napoleon Bonaparte, Rumford left England for France. In his absence, the Royal Institution developed into a premier applied research facility.

In Paris, Rumford courted and married the widow of the French physicist Antoine Lavoisier, although they separated not long after. As he aged, Rumford's ego and temper worsened. His archconservative views on race and democracy also did little to encourage friendships, and he was soon ostracized from France's scientific community. He continued to conduct research and tinker with inventions but created nothing of great value in France. He died there in 1814.

Three-Piece Iron Plow

In 1807, a decade after Charles Newbold earned the first American patent for the iron plow, a man named David Peacock received a patent for his new cast-iron plow. While Newbold's plow had been cast in one piece, Peacock's was cast in three separate pieces. Charles Newbold eventually sued Peacock for patent infringement, receiving damages for the ordeal. Peacock's plow was not different enough to have its own patent, but it did put forth a new idea that would shape American technology.

The three-piece iron plow first found use as a replacement for digging sticks in ancient civilizations such as Egypt and Confucian China. It gave farmers an increased ability to break up soil, bury crop residues, and help control weeds. Farmers in these ancient civilizations began using metal-bladed plows and could use oxen and horses to pull them. While plows were made completely out of iron in China, their designs did not make it to Europe until much later.

With the early stages of American industrial growth came a need for increased farming production. The majority of American farmland was in the Midwest, which was covered with black prairie soil. To compensate for the tough terrain, the wood of plows was sheeted in metal. This was an improvement that made plows more durable. Even though it was now a more durable tool, it was very heavy. Newbold fixed this problem through his studies of cast iron. He was able to cast a plow without using a wooden base, making the contraption lighter, and adding the handles and beam afterward. This new plow was stronger and lighter than any plow had been, but it was not indestructible. The cast iron wore down, making it susceptible to easy breaks. Peacock's invention did not change the material that was used, but it changed the configuration, splitting the plow into three distinct pieces. If Newbold's plow broke down, an entire new plow had to be cast, but if Peacock's plow broke down, the piece that was affected could be replaced.

None of these creations made a fortune for their owners until steel was first used by John Deere in 1833, but that does not diminish their importance. The

three-piece plow gave way to the creation of increasingly complex machines, with the idea that if something broke, the part could be replaced instead of the entire machine. This principle is still used to this day in all forms of technology. David Peacock did not necessarily discover the idea of separation of parts, but he did use the idea in a very practical and functional way.

Primary Document: Petition to Congress Asking for a Renewal of the Patent on Jethro Wood's Cast-Iron Plow (1846)

In 1846, Jethro Wood's heirs presented to the 29th Congress a petition proving the worth of the cast-iron plow and asking for a renewal of the patent for the invention. The excerpt here describes the process whereby Wood came to invent that plow.

Humbly Sheweth:

That jethro wood, deceased, husband of said executrix, and father of said executor, was a man of limited education but of philosophic mind and very benevolent disposition.

About the year of 1813, being a farmer, in was induced to believe that agriculture was very much hindered by the defects in the chief instrument of tillage, the plough. From that period he dovoted himself for six years to the improvement of that important instrument. The plough then in use in Europe and in Amerca was constructed chiefly of unwieldy timbers, in a form which presented great resistance to progress and tof coure requiring very great power. These ploughs had always a heave wrought iron share, made at great expense and requiring frequent and expensive repairs.

Jethro Wood instituted, at great expense, a series of experiments with ploughs of various frms and properties, as to length, height, width and curvature of the mould board, and thickness of the plow share. He constructed many ploughs with his own hands and tested their forms and usefullness in various regions of the country, presenting varieties of soils.

He set for himself three objects:

First. to discover a form of the plough which would perform the work desired in the easiest and best manner.

Secondly. To produce a diminution of the cost of contruction.

Thirdly. Durablility of the instrument.

He had discovered that the mold board of every plough then known presented a surface unequally worn or polished by use.

Before Jethro Wood's invention cast iron ploughshares were unknown. Ever farmer remembers the expense and trouble of carrying the wrought iron ploughshare to the blacksmith every two or three weeks to procure the same to be sharpened and relaid. Mr. Wood suggested to a community, who were so incredulous that it required four or five years of constant demonstration to satisfy them, the use of light cast iron share or cutting edge, nicely adjusted, fastened to the mould board, which was extended for that purpose. The experiment, as it was known, was ultimately successful; and now, it is doubted whether a wrought iron ploughshare can be found in use in the world.

Vapor-Compression Refrigerator

In 1805, American inventor Oliver Evans first described a closed vapor-compression refrigeration cycle to produce ice by ether under vacuum. He described it as heat that would be removed from the environment by recycling vaporized refrigerant where it would compress and condense so it could repeat the process over again. Vapor compression is the most commonly used method of cooling.

However, Evans was not the person who created the refrigerator. In 1834, an American expatriate to Great Britain, Jacob Perkins, built the first working vapor-compression refrigeration system in the world. His prototype system worked, although it failed commercially. The first practical vapor-compression refrigeration system was built by James Harrison, who was a British journalist who emigrated to Australia. His patent in 1856 was for a vapor-compression refrigeration system using ether, alcohol, or ammonia.

The vapor-compression refrigeration cycle is approximately a Rankine cycle run in reverse. A working fluid is pushed through the system and undergoes state changes. There are four parts in the refrigeration process.

In the compression stage, the refrigerant enters the compressor as a gas under low pressure and low temperature. Then the refrigerant is compressed adiabatically, so the fluid leaves the compressor under high pressure and with a high temperature. Condensation is the second stage. In this stage, the high-pressure, high-temperature gas releases heat energy and condenses inside the condenser. The refrigerant leaves as a high-pressure liquid. In the throttling stage, liquid refrigerant is pushed through the throttling valve, which causes it to expand. Thus, the liquid refrigerant is now a low-pressure and low-temperature fluid. The last stage is refrigeration. The low-pressure, low-temperature refrigerant enters the evaporator, which is in contact with the cold reservoir. Because a low pressure is maintained, the refrigerant can boil at a low temperature. It moves back into the compressor, and the cycle starts all over again.

Many refrigerators today use the same process as in the 1800s.

Waltham-Lowell Textile System

The Lowell system, also known as the Waltham-Lowell system, was a vertically integrated labor production model implemented in the U.S. textile industry from 1814 to the 1830s. It was developed by Massachusetts-born entrepreneur Francis Cabot Lowell (1775–1817), who had envisioned a highly efficient method of combining the capabilities of many modern inventions of the time (such as the cotton gin, spinning jenny, and water frame) to control all textile production aspects under one roof. Lowell was inspired by an 1811 visit to Great Britain, where he witnessed the products of the Industrial Revolution.

Prior to the advent of the Lowell system, the textile industry of the United States operated by the Slater mill system, or Rhode Island system, modeled by British immigrant William Slater and implemented in Rhode Island in the 1790s. Under this model, mills arose in villages of workers brought in from abroad; often poor, landless families and children. Different villages would specialize in one particular aspect of production: wool was gathered in one village, then sent to another to be spun into cloth. Spinning in the United States was still done with looms powered by foot pedal, as opposed to the power looms in Britain powered by waterwheels.

When Lowell returned from Britain, he and a group of investors called the "Boston Associates" formed the Boston Manufacturing Company in 1813 and opened its first mill along the Charles River in Waltham, Massachusetts, in 1814. This signaled the inception of Lowell's model, a vertically integrated system in which the entire process of textile production—from raw fiber

to finished cloth—was completed within a single location. Combined with power looms modeled after the British system, the result was mass production with a sufficient amount of control to prevent interference in production from outside sources. In fact, the rapidly growing scale of production exceeded the input of localized labor forces available to the mills.

To compensate, Lowell hired young women ages 15 to 35, promising better conditions than those of farm labor. They resided in boardinghouses, were kept to a strict routine overseen by older women, and adhered to a rigid moral code that included mandatory religious service. In an attempt to distinguish his business from the exploitative ones of Britain and Rhode Island, Lowell avoided child labor, paid workers in cash, and provided avenues for his “Mill Girls” to educate themselves.

Lowell died in 1817, and the Lowell system went into decline in the 1830s as cotton overproduction deflated the price for finished cloth, and immigrant labor (fueled especially by the Irish potato famine) replaced the Mill Girls. With the second generation of mill managers lacking Lowell’s idealism, the New England textile industry began resembling its counterparts in Britain and Rhode Island. Lowell is still remembered for his pioneering factory model and for effectively bringing the Industrial Revolution to the United States.

Wheel Cipher

The wheel cipher was invented by Thomas Jefferson in 1795 while he was serving as U.S. secretary of state. While the device was likely the most advanced cryptographic instrument of its time, it proved impractical in

everyday use and was forgotten. A version of Jefferson’s invention proved so difficult to decode that it remained in U.S. military use during World War II.

Thomas Jefferson was well acquainted with ciphers and codes; as ambassador to France and then secretary of state, he had been determined to prevent his secret communications from being read. He used the 16th-century Vigenère cipher throughout his career, but he was familiar with many other ciphers, including a wheel-based cipher invented by Leon Alberti in 1467. Jefferson improved this design and created a cipher superior to any other of its time.

The wheel cipher he invented was deceptively simple; it was a series of 36 cylinders with the alphabet and numbers etched along their rims. The cylinders were arranged on a spindle in a random order. Users would then line up the symbols for the letters they wanted to code and pick a separate line. If the reader had an identical device with the cylinders arranged in the correct order, he or she could simply duplicate those characters and look for the line that had plain text.

The wheel cipher was simple to use but virtually impossible to decode. Without the cylinders in correct order, there were 4.7×10^{45} possible combinations. It was a remarkable achievement, one that surpassed virtually any other system of predigital encryption. However, there were drawbacks. In an age before machine tools, the wheel cipher required careful craftsmanship. The final product had to be transported to its destination by courier, and there had to be a system for determining the correct order of cylinders. In 1795, during treaty negotiations with Britain and with a war against France a distinct possibility, Jefferson needed a more practical, if less secure, means of encryption.

As a result of these concerns, Jefferson abandoned his wheel cipher design and embraced a less complex cipher. His first design was forgotten in the archives at Monticello for over a century, but similar devices were reinvented at least twice. In the late 19th century, the French cryptographer Étienne Bazeries created a similar device. The U.S. military’s Col. Parker Hitt independently created a wheel cipher that became known as the M-94. The M-94 was used throughout World War II for tactical communications and is not much

less complex than ciphers still in use by the U.S. military. Jefferson's writings on the wheel cipher were rediscovered shortly after the M-94 entered service in 1922.

Primary Document: Excerpts from Thomas Jefferson's Notes on the Wheel Cipher (Undated)

While serving as U.S. secretary of state (1790–1793), Thomas Jefferson devised the wheel cipher, a clever and secure method to encode and decode diplomatic messages. Jefferson had learned, while serving as American minister to France (1784–1789), the importance of encoding his diplomatic correspondence, for European postmasters routinely opened and read all diplomatic messages and any suspect letters passing through their offices. Reproduced here is an excerpt from Jefferson's undated notes on the construction of a wheel cipher.

The Wheel Cypher

Turn a cylinder of white wood about 2 l. diam. and 6. or 8 l. long. Bore through it's center a hole sufficient

to receive an iron spindle or axis of $\frac{1}{2}$ or $\frac{1}{4}$ l. diam. Divide the periphery into 26 equal parts (for the 26 letters of the alphabet) and with a sharp point draw parallel lines through all the points of division from one end to the other of the cylinder and trace those lines with ink to make them plain. Then cut the cylinder crosswise into pieces of about $\frac{1}{6}$ of an Inch thick. They will resemble backgammon men with plane sides. . . .

Whitney, Eli (1765–1825)

Eli Whitney was a late 18th- and early 19th-century American inventor whose work had an incalculable and wide-ranging impact on the development of the United States. While the creative Whitney is credited with a number of inventions that impacted numerous areas of American life, it was his invention of the cotton gin, a device that revolutionized the economy of the American South, that had the greatest impact on the young nation.

Eli Whitney was born on December 8, 1765, in Westboro, Massachusetts, to Eli Whitney Sr. and the former Elizabeth Fay. From an early age, he showed an exceptional instinct for handling mechanical things, demonstrating an uncanny understanding of how they

worked. A big man, he first worked as a blacksmith, but the young inventor and entrepreneur demonstrated an early understanding of markets when he began manufacturing and selling nails to Americans whose previous supply lines from Great Britain had been limited by a series of boycotts and embargoes. Recognizing a consumer desire, he also expanded his manufacturing efforts to include women's hat pins—becoming the only manufacturer in the country of yet another item impacted by trade limits. He was both an astute businessman and a skilled craftsman.

Despite his mechanical skills, Whitney desperately wanted to attend college, an institution that at the time focused on preparing men for either the law or the pulpit. While he professed to want to pursue the law, it was still against his parents' wishes that the young

Though Eli Whitney is most famous for inventing the cotton gin, an apparatus he actually coined with Catharine Littlefield Greene, his most important contribution to American technology is his work with interchangeable parts. (Library of Congress)

inventor attended Yale College, graduating in 1792 at the advanced age of 27. His initial dream of becoming a lawyer was hampered by a lack of money, and in an effort to secure the needed funds, he accepted a position as a tutor in South Carolina. Fortuitously, among the few passengers on the transport carrying Whitney was Mrs. Nathanael Greene, the widow of General Nathanael Greene, the Revolutionary War hero, who was traveling back to her home in Savannah, Georgia, and they became acquainted. Upon arriving in South Carolina, Whitney was greeted with the news that his salary for tutoring would be half of what had been promised. Indignant, he refused the offer and instead accepted an invitation from Mrs. Greene to come to her plantation, read law, and help in whatever way he could the plantation manager, Mrs. Greene's fiancé, Phineas Miller, who was also a Yale alumnus.

Upon arriving at the plantation, it took the astute Whitney little time to recognize the labor problem

inherent in the tedious and inefficient process of extracting fiber from cotton by hand. With the support of Mrs. Greene, he worked during the winter to develop what became the cotton gin. The machine's unveiling, as well as its early demonstrations, were met with an immediate and positive response, and its potential was recognized at once. Indeed, so popular and effective—and so comparatively simple—was the new machine that despite the patent that Whitney ultimately obtained, Whitney and Miller saw little substantive profit, certainly nothing approaching what they had hoped and rightfully anticipated. Indeed, despite a series of legal battles, the machine was pirated, copied, and used all over the South. Ultimately, the primary legal fight over the patents for the cotton gin was settled in 1807, and while Whitney was established as the inventor of the cotton gin—a fact that did bring him considerable fame—the \$90,000 he collected was not a significant reward.

Indeed, he ultimately became so frustrated with the tangle of legal action that he all but abandoned the effort to secure his rights and instead, in severe financial straits, turned his attention to the development of interchangeable parts. With the threat of a possible war with France looming, Whitney got a government contract for 10,000 rifles in 1798. While he was unable to meet the contract in time, he eventually did meet it in amount while also earning another large contract. In the course of fulfilling those orders, he developed his system of interchangeable parts, an idea that did not originate with him but that, befitting his considerable talents as a salesman and marketer, he made commercially practicable. In the end, though, Whitney largely failed to meet his contractual obligations and indeed may have conned government officials into believing he'd accomplished more than he had. Whitney engaged in this duplicitous business practice to financially benefit from the idea of interchangeable parts, in part because he felt he had not been as well compensated for the cotton gin as he deserved.

In addition, while it remains a source of contention among historians, Whitney is often credited with inventing the milling machine, a vital advancement in early 19th-century craftsmanship. In reality, a number of inventors were working on grain-milling machines at the same time in the 1810s, and historians believe that no one person can be credited with the invention.

A longtime bachelor, in 1817, Whitney married the former Henrietta Edwards, the granddaughter of prominent religious leader Jonathan Edwards and a member of a respected Connecticut family. The couple had four children. Whitney died on January 8, 1825, in New Haven, Connecticut. He is buried in the Grove Street Cemetery in New Haven. The cause of death is believed to have been prostate cancer. Ever the inventor, while fighting that disease, he invented and built a number of mechanical devices that were effective in easing the pain, but his family's opposition prevented him from manufacturing any of the items.

Whitney may be one of the most famous of American inventors, but much of the popular history about him and his most famous invention is incorrect or incomplete. Catharine Littlefield Greene remains largely forgotten for her part in the invention of the

cotton gin. History also often fails to record the human misery that the cotton gin created by breathing new life into cotton growing and thus American slavery.

Primary Document: Letter of Eli Whitney to His Father Regarding the Ginning of Cotton (1793)

The following is a letter that Eli Whitney wrote to his father in 1793 after his trip to Georgia, where he discerned the difficulty in ginning cotton and began devising a plan for a machine to address the problem. The reader can see young Whitney's confidence in his idea in this letter.

Eli Whitney to Eli Whitney, Senr
New Haven, Sept. 11th, 1793.
Dear Parent,

I received your letter of the 16th of August with peculiar satisfaction and delight. It gave me no small pleasure to hear of your health and was very happy to be informed that your health and that of the family has been so good since I saw you. I have fortunately just heard from you by Mr. Robinson who says you were well when he left Westboro sooner than I now fear will be in my power. I presume, sir, you are desirous to hear how I have spent my time since I left College. This I conceive you have a right to know and that it is my duty to inform you and should have done it before this time; but I thought I could do it better by

verbal communication than by writing, and expecting to see you soon, I omitted it. As I now have a safe and direct opportunity to send by Mr. Robinson, I will give you a summary account of my southern expedition.

I went from N. York with the family of the late Major General Greene to Georgia. I went immediately with the family to their Plantation about twelve miles from Savannah with an expectation of spending four or five days and then proceed into Carolina to take the school as I have mentioned in former letters. During this time I heard much said of the extreme difficulty in ginning Cotton, that is, separating it from its seeds. There were a number of very respectable Gentlemen at Mrs. Greene's who all agreed that if a machine could be invented which would clean the cotton with expedition, it would be a great thing both to the Country and to the inventor. I involuntarily happened to be thinking on the subject and struck out a plan of a Machine in my mind, which I communicated to Miller, (who is agent to the Executors of Genl. Greene and resides in the family, a man of respectability and property) he was pleased

with the Plan and said if I would pursue it and try an experiment to see if it would answer, he would be at the whole expense, I should loose nothing but my time, and if I succeeded we would share the profits. Previous to this I found I was like[ly] to be disappointed in my school, that is, instead of a hundred, I found I could get only fifty Guineas a year. I however held the refusal of the school untill I tried some experiments. In about ten Days I made a little model, for which I was offered, if I would give up all right and title to it, a Hundred Guineas. I concluded to relinquish my school and turn my attention to perfecting the Machine. I made one before I came away which required the labor of one man to turn it and with which one man will clean ten times as much cotton as he can in any other way before known and also cleanse it much better than in the usual mode. This machine may be turned by water or with a horse, with the greatest ease, and one may and a horse will do more than fifty men with the old machine. It makes the labor fifty times less, without throwing any class of People out of business.

I returned to the Northward for the purpose of having a machine made on a large scale and obtaining a patent for the invention. I went to Philadelphia soon after I arrived, made myself acquainted with the steps necessary to obtain a Patent, took several of the steps with Secretary of State Mr. Jefferson agreed to send the Patent to me as soon as it could be made out—so that I apprehended no difficulty in obtaining the Patent—Since I have been here I have employed several workmen in making machines and as soon as my business is such that I can leave it a few days, I shall come to Westboro'. I think it is probable I shall go to Philadelphia again before I come to Westboro', and when I do come I shall be able to stay but few days. I am certain I can obtain a patent in England. As soon as I have got a Patent in America, I shall go with the machine which I am not making, to Georgia,

where I shall stay a few weeks to see it at work. From thence I expect to go to England, where I shall probably continue two or three years. How advantageous this business will eventually prove to me, I cannot say. It is generally said by those who know anything about it, that I shall make a Fortune by it. I have not expectation that I shall make an independent fortune by it, but think I had better pursue it than any other business into which I can enter. Something which cannot be foreseen may frustrate my expectations and defeat my Plan; but I am now so sure of success that ten thousand dollars, if I saw the money counted out to me, would not tempt me to give up my right and relinquish the object. I wish you, sir, not to show this letter not communicate anything of its contents to any body except My Brothers and Sister, *enjoining* it on them to keep the whole a *profound secret*.

Mr. Robinson came into town yesterday and goes out tomorrow, this has been such a bustling time that I have not had opportunity to say six words to him. I have told him nothing of my business—perhaps he will hear something about it from some body else in town. But only two or three of my friends know what I am about tho' there are many surmises in town—if Mr. Robinson says anything about it, you can tell him I wrote you concerning it, but wished not to have it mentioned. I have been considerably out of health since I wrote you last; but now feel tolerably well. I should write to my Brothers and Sister but fear I shall not have time—hope they will accept my good wishes for their happiness and excuse me.

With respects to Mama I am, kind Parent, your most obt. Son

Eli Whitney, Junr.

3. Antebellum Industrialization and the Civil War (1820–1865)

OVERVIEW

The 45-year period between 1820 and 1865 was characterized by tumultuous economic, social, and political transformation in the United States. During this time, American industrial and scientific development coincided with the rise of Jacksonian democracy and an emphasis on egalitarian economic independence. The Industrial Revolution was preceded by a rapid increase of population that came as a result of the agricultural revolution; it converged with four distinct moral reform impulses that included the creation of utopian societies (1820), institutional reform (1830s), the abolition movement (1830s), and the early women's rights movement (1840s). An increasing interest in developing educational opportunities for advanced training in applied science, agriculture, and engineering emerged to address the needs of the nation. Perhaps the most significant advancement during this era was the electronic telegraph, since it became the first communications medium to radically break the historic connection between transportation and communication, creating a new industry that transformed information from a personal possession to a global commodity. Industrial interests countered the traditional centering of populist values within the agricultural sector as technological advancements reshaped American economic foundations, enabling the nation to adapt despite a financial panic in 1837 and the first great industrial economic depression that occurred between 1839 and 1843.

Western industrialization was first developed in Europe after Scottish engineer James Watt (1736–1819) developed the double-acting steam engine that fostered factory manufacturing during the late 18th

century. America was not prepared to develop industrial infrastructures until after the War of 1812, because it was still dependent upon Great Britain culturally and economically. The thinking of American economist and publisher Henry Charles Carey (1793–1879) informed American approaches to industrialization. Carey was the son of publisher Matthew Carey (1760–1839), a contemporary of Founding Father Alexander Hamilton (1755–1804), who had earlier been the architect and founder of the American financial system and the first secretary of the Treasury, among many other firsts. Henry Carey took over control of his father's publishing house but made his own mark as a political scientist who promoted laissez-faire, free-trade capitalism. Carey was a proponent of fostering nationally connected, government-protected "associations" for capitalistic production and exchange that advanced Hamilton's work. Hamilton had earlier created a government-backed Bank of the United States that was funded by import tariffs and mobilized a nationwide network of bankers and businessmen friendly to the young "experiment" in democratic government that became known as the Federalist Party. Hamilton had sought to protect government and assist business manufacturing by strategically levying protective duties on foreign-manufactured goods as well as curtailing certain import duties on raw material; Carey leveraged this logic forward through the antebellum period to the Civil War era when he served as Abraham Lincoln's chief economic advisor.

Some of the major inventions came from amateurs; American industrialization would not have occurred without scientific innovators who produced creative visions that motivated entrepreneurs to turn creative imaginings into reality. British physicist and

chemist Michael Faraday (1791–1867), for instance, was considered to be an amateur and had little formal education, yet he discovered benzene and electromagnetic induction, made the first dynamo, and erected a primitive electric motor. Faraday compensated for his lack of mathematical prowess with what Marshall McLuhan called a “fantastic intuition and independence and originality of mind” (McLuhan 1967, 92). But many shifts from enthusiast to professional status occurred in the scientific community throughout the antebellum era. To sustain power in the marketplace, scientists asserted a type of sovereignty by building a “fortress of objectivity”: utilizing scientific rhetoric, they “proved” that their interpretations of the visible universe should govern everyone’s understanding of the world.

Religious Revivals and American Innovation

The Second Great Awakening gained momentum concurrent to the emerging utopian vision that was a reaction to rapid industrialization; it fueled a sensibility that Christianity was the foundation of the egalitarian engine of social progress and set new boundaries for commerce. A dichotomy of thought and action between moral reforms and commercial enterprise created tensions that resulted in a cultural dearth of ideas and ideologies that was destined to culminate in civil war. The American government asserted authority over its continent with the Monroe Doctrine (1823); it also declared that European interference in the Western Hemisphere was dangerous to peace and safety and that the United States would not become involved in European conflicts.

Soon after, mechanics’ institutes were established in urban areas as to educate working men interested in technical subjects and to address society’s need for scientific knowledge. This fostered the field of engineering. Concurrent was the Lyceum Movement in the United States that started in a textile-manufacturing town called Millbury, Massachusetts, in 1826. These institutes were a response to a new class of reader as a result of industrialization, and they created unprecedented access to science and technology information. Men who could not afford subscription libraries could attend lecture courses at lyceums and gain access to

laboratories at mechanics’ institutes. Meanwhile, textile manufacturing created affluence in the Northeast, particularly in Massachusetts. Other forms of manufacturing also became booming industries, including in iron, textiles, and flour mills in the Mid-Atlantic states.

Between 1836 and 1840, the Transcendental Movement arose in the United States, led by thinkers including Frederic Henry Hodge, Ralph Waldo Emerson, Bronson Alcott, Orestes Brownson, Henry David Thoreau, Margaret Fuller, Elizabeth Peabody, and many more. Transcendentalism became the first homegrown American intellectual movement—similar to Romanticism in Europe—that emerged during the late 1820s, when New England thinkers discerned that the institutions of organized religion and political parties could be vectors for corrupting an individual’s innate purity.

Marketplace Innovators

The Industrial Revolution fostered a nation of “creative thinkers” who synthesized and built upon new ideas in the marketplace. These innovators did not have to be *the* actual scientific genius who created the product. The ability to shape a vision around an idea or set of ideas and communicate them to those who would manufacture the product was enough for success. The decade of the 1830s brought about some fundamental building blocks for industrial advancement. Thaddeus and Erastus Fairbanks developed the platform scale, also known as the Fairbanks Scale, in 1830. This bench scale measured the counterbalanced weight of loaded objects at ground level and therefore did not need to use a hoist. Fairbanks scales were the best-known American product in the world by the time the Civil War started. Robert L. Stevens (1787–1856), while president of the Camden & Amboy Railroad, developed the flanged *T* rail in 1831, an all-iron rail that had a flat bottom, requiring no chair to hold it upright. William Otis (1813–1839) invented the steam shovel, a large steam-powered excavating machine designed for lifting and moving material such as rock and soil, typically used in the mining industry, in 1835. The shovel was applied in building railroads. William Austin Burt (1792–1858) developed a solar compass in 1835 with a solar attachment that allowed surveyors to determine the direction of north by reference to the sun rather

than to a magnetic needle. This railroad compass consists of three arcs: one for setting the latitude of the land to be surveyed, one for setting the declination of the sun, and one for setting the hour of the day.

French political writer Alexis de Tocqueville (1805–1859), in *Democracy in America* (1835), observed that Americans tended to be independent, stand-alone citizens who believed that they held their individual destinies in their own hands. Nothing made this more of a reality than communication innovations during the mid-1830s. The penny press became an affordable and economically savvy way to spread information and political views to the masses. The first American daily newspaper was the *New York Herald*. With the telegraph, news could spread like wildfire, conveying opportunities that created instant boomtowns.

Joseph Henry (1797–1878) developed an electrical switch known as a relay that opens and closes under the control of another electrical circuit; this was applied in the electrical telegraph. Alfred Vail (1807–1859) and Samuel Morse (1791–1872) developed a signaling alphabet in 1836 known as Morse code that encoded characters transmitted as telegraphic information using rhythm. Richard Hoe (1812–1886) ignited a revolution in printing by developing the rotary printing press; it prints images by utilizing a curved cylinder. Royal Earl House (1814–1895) developed the printing telegraph in 1846, a derivative of the electrical telegraph that links two 28-key piano-style keyboards by electrical wires corresponding to letters of the alphabet. When a key is pressed, it causes the corresponding letter to print at the receiving end. This is in contrast to the electrical telegraphs that used Morse code's dots and dashes, which needed to be converted into readable text after they were received. After 1850, the printing telegraph was in common use, namely along the United States' East Coast and in France.

These new communications technologies meant that for the first time, communication traveled faster than humans could move. Therefore, the condition of being literate—able to read, write, and be skillful in the use of words—was seminal to sustaining this industrial revolution: only a knowledgeable populace can test and innovate ideas. The notion of “self-education” fostered by literacy went to the core of American cultural

identity that came out of the First Great Awakening: the self-made man. Within the broader idea of “enduring democracy,” where government by the people is exercised either directly or through elected representatives, a populace that is well read and knowledgeable became mandatory. While today literacy does not have a color bar, in the past it did. If any group was intentionally excluded from literacy education, it was effectively disenfranchised. Literacy was tied to identity and became part of the American national identity. Illiteracy within a society reflects an “educational underclass,” with symptoms seen in the disposed of: the homeless, the unemployed, and families on welfare. Economic interests and social control have driven literacy in America: industries with low-skilled workers have not required an educated workforce, but highly skilled jobs require highly literate workers.

Literacy, Standardization, and True Womanhood

Prior to the American Revolution, women were literate enough to teach young children but not enough to challenge male heads of household. During the Early Republic, American Lexicographer Noah Webster (1758–1843) led the movement to standardize the spelling and punctuation of the English language in the United States. He published *The American Spelling Book* (1783) to promote American nationalism and cultural independence from England. In westward expansion, public education was limited, so literacy education occurred at home, in one-room (common) schools, and in church-based education programs. American educator Horace Mann (1796–1859) developed common schools during the antebellum era to support the dramatic cultural changes that were unfolding. Common schools grouped students by grades that employed systematic, mechanical, lock-step teaching of “the three Rs” (reading, [w]riting, and [a]rithmetic), along with history and geography.

Patents provide government license that confers the right or title for a set period of time to exclude others from making, using, or selling an invention in exchange for public disclosure of that invention. The process of patenting was designed so that inventions get explained clearly so that others can build upon the

ideas in them. The value of disclosing an invention's technical details, within the context of patent theory, is that it fosters the prompt inclusion of useful knowledge into the public knowledge banks, reduces research-and-development waste, spurs creative innovation, and leads others to engage with the patentee's work to produce improvements or wholly new innovation, thereby extending industry frontiers.

The Patent Act of 1836 created an official United States Patent Office as part of the Department of State. Politician John Ruggles (1789–1874), during his tenure as a Democratic senator from Maine, served as chairman of the Committee on Patents and the Patent Office and framed a bill to reorganize the Patent Office. (He became known as the “Father of the U.S. Patent Office.”) The act allowed for the efficient processing of patent applications and prevented applications for already patented inventions by requiring information on newly granted patents to be made publicly accessible at libraries throughout the country. Anyone could consult this information to check whether inventions were truly original before filing for a new patent. The act allowed for a possible extension of 7 years of protection in addition to the original 14-year term with the permission of the Commissioner of Patents. It also removed the requirement of U.S. citizenship and residency, making it possible for foreigners to file for U.S. patents. Patent Number 1 was granted to Ruggles on July 13, 1836, for his invention: a type of train wheel designed to reduce adverse effects of the weather on the track.

Capitalism drove American politics as individuals sought opportunities to accumulate wealth continuously. A paternalist aesthetic had historically assumed that husbands, fathers, brothers, and sons would act and make decisions in the best interests of their dependents. A homeless man was considered a dependent just as a slave was; he was not obliged to pay property taxes. If he was clever, he could make his way by bartering services for food and temporary shelter. But the transient, who did not pay taxes, was disenfranchised as well as dependent upon the generosity of others. Those who lived on the fringes of society found themselves in the path of an industrial juggernaut.

At the same time, women's lives were changing, too, according to historian Barbara Welter. She wrote about the “cult of true womanhood”—a sensibility held between 1820 and 1860 that American women were expected to pursue lives of sheltered passivity and ennobled domesticity. In the “private” sphere, middle-class women held authority over moral and family issues and were expected to create an antimaternalistic world within the home that balanced the sordid male world of public life. Emma Willard (1787–1870) established the Troy Female Seminary in 1821 to educate girls to be responsible mothers and to become teachers. Catherine Beecher (1800–1878) wrote her *Treatise on Domestic Economy* (1841) to promote an educational scheme to professionalize female schooling in domestic work in the private, female sphere to mirror masculine training to enter the public, male sphere. Transcendentalist Elizabeth Palmer Peabody (1804–1894) was the first American woman to become a publisher; she had a bookstore in her Boston home from about 1840 to 1852 and edited the Transcendentalist publication called *The Dial* beginning in 1843. Harriet Beecher Stowe (1811–1896) wrote *Uncle Tom's Cabin* (1852), which brought controversial aspects of slavery into popular culture and the nation's consciousness.

Some women began to shift from housework to economically accountable work in textile manufacturing. While men held the management positions in this industry, women and children worked on its production lines. Men earned higher wages in comparison to women, so women were not only paid less but also expected to work unreasonable hours in detrimental conditions with only a few breaks a day. Yet, the textile manufacturing industry served as a gateway to independence for single women, who could become economically self-sufficient, move out of their parents' households, and become somewhat upwardly mobile.

Mechanic Walter Hunt (1796–1859) invented the first lockstitch sewing machine in 1833. In this machine, an upper thread runs from a spool kept on a spindle on top of or next to the machine, through a tension mechanism, a take-up arm, and finally through the hole in the needle. The lower thread is wound onto

a bobbin, which is inserted into a case in the lower section of the machine. Hunt did not apply for a patent to avoid creating unemployment among seamstresses, until Elias Howe (1819–1867) developed the transverse shuttle in 1846 as a method to drive a bobbin on a sewing machine so as to create the lockstitch technique.

Agricultural Innovation and the Challenge of Slavery

Innovations did not confine themselves to urban centers and factory technology. Hiram Moore (1817–1902) invented the first combine harvester in 1834 that combined the tasks of harvesting, threshing, and cleaning grain crops. Blacksmith John Deere (1804–1886) modernized the plow in 1837 by shaping steel from an old sawmill blade and joining it to a wrought-iron moldboard, creating a self-polishing cast-steel plow so that damp soil would no longer stick to it. These inventions revolutionized agricultural work.

The rapid pace of industrialization caused some to worry about what the new type of work did to workers. Transcendentalism provided a powerful counterpoint to antebellum capitalism. New England Transcendentalist Orestes Brownson (1803–1876), in a series of essays called “The Laboring Class,” published in the *Boston Quarterly Review* in 1840, observed during America’s first sustained industrial depression that there was a correlation between motives of capitalists in leadership positions across American industries within the evolving laissez-faire economic model. These capitalists, who controlled the wealth, oppressed the laboring class to a crisis point, and the work ethic of laborers was exploited for the profit of the merchant class. In 1844, another Transcendentalist, Ralph Waldo Emerson (1803–1882), identified the locomotive and steamboat transportation industries as creating a seamless web of American society. The construction of railroads, canals, turnpikes, and steamboats, beyond fostering human mobility, made the transportation of goods more efficient; it created jobs and made travel much easier by connecting the East Coast to the West Coast.

John L. O’Sullivan coined the phrase “manifest destiny” in 1845, asserting that it is the “right of our

manifest destiny which Providence has given us for the great experiment of liberty and federated self-government entrusted to us.” Direct democracy and its checks and balances tested the capabilities of the more malleable society composed of diverse interest groups, each with their agendas.

Meanwhile, in Europe, with such dramatic technological change, unskilled workers faced 12- to 15-hour days—when they could find employment—and lived in disease-ridden slums. Artisans lost their guilds; they were crushed by the industrial juggernaut. Subsequent to several harvest failures, urban workers spent about half of their incomes on food—which primarily consisted of bread and potatoes. This led to a series of failed European revolutions in 1848 led by coalitions of reformers, the struggling middle class, and workers. Conversely, the American middle class was the fastest-growing group during the antebellum period. Immigrants and female factory workers were occupied in harsh and dangerous conditions with low wages. These groups were only offered work as cheap labor. Nativists—those who sought to protect the interests of native-born inhabitants against those of immigrants—became hostile toward immigrants, whom they perceived as taking jobs from Americans. The Know-Nothing Party emerged as part of the Nativist reaction to immigration.

At the start of the Civil War, less than 5 percent of Americans of African descent were literate. The South was still based economically on agricultural advancements because of the free labor and fertile soil. Slavery appeared to be primarily focused in the South by 1830; however, Native American women could legally be indentured—sold into slavery—if captured, a practice that continued until the Civil War. African Americans were enslaved on small farms, large plantations, in cities and towns, inside homes, out in the fields, and in industry and transportation.

Charles Carey published *The Harmony of Interests: Agricultural, Manufacturing, and Commercial* (1851), which described an American sensibility of developmental capitalism that utilized tariff protection and government intervention to encourage production and national self-sufficiency. Carey was a proponent of the ideal of harmony of interests among

agriculture, manufacturing, and commerce. He felt that government intervention was necessary to foster industry in younger, experimental communities created by the actions of older and wealthier nations. In Carey's later work, *The Principles of Social Science* published in three volumes, he sought to show that independent of human will, a natural system of economic laws exists that can increase the prosperity of the community, especially in the working classes, except when it is impeded by the ignorance of humankind.

Yet in the pre-Civil War South, enslaved people were considered property. This status was enforced by violence; beyond this, they were considered to be dependents. The Dred Scott legal decision (1857) ruled that African Americans had no claim to freedom or citizenship; they were considered property and therefore could not bring lawsuits or testify against those classified as white in court. Therefore, the power imbalance under the Southern plantation economy grew. Nonslaveholding white Southerners identified with and eventually defended the institution of slavery although many resented the wealth and power of the large slaveholders. Slavery provided poor farmers a sense of power and entitlement simply because they were classified as white. They might have been poor, but they were not enslaved, and they were not of African descent.

Gold Rush Failures

The economics of the California Gold Rush (1848–1855) blended capitalism, individualism, and early forms of futures speculation. The estimated \$2 billion in gold extracted from California soil stimulated a tumultuous global economy. The U.S. government awarded the Pacific Mail Steamship Company, established in 1848 as a joint stock company, exclusive rights to transport mail via the Isthmus of Panama to California, creating a communications monopoly. San Francisco became a hub for inept capitalism and greed that actually disbursed wealth to other regions of the globe during 1848, the “year of failed revolutions.” Ordinary men squatted and remained disenfranchised when they could not acquire land through legitimate means. Felice Argenti (1802–1861), a patriot of the

Risorgimento from Viggiù in Lombardy (known by his Americanized name, Felix Argenti), operated the largest bank in San Francisco before Wells Fargo was established in 1852. Argenti charged high “loan shark” interest rates. California banks were not regulated until the State Revenue Act, passed May 18, 1853, levying 10 cents for every \$100 of business transacted, so speculators like Joseph Libbey Folsom (1817–1855) purchased and developed land utilizing credit lines and sometimes dubious means.

Antebellum industrialization could bring about rough sport. Politics dictated who controlled resources and the circumstances by which California entered the Union in 1850 at the peak of the Gold Rush boom. Individuals involved with slavery (which gave Southern white males an unfair advantage in the goldfields) were challenged based on the assumption that control of property and labor impacted political agency. The Fugitive Slave Act, or “Compromise of 1850,” included concessions to pro-slavery forces needed to gain the admission of California to the Union. This Act created an infrastructure to capture escaped slaves living in free territories yet often freeborn individuals of African ancestry not carrying freedom papers could be seized and sold into slavery. Slave owners were permitted to travel through free states, including California, with slaves (considered to be servants), but if a slaveholder resided there, then their slaves could leave. Throughout the 1850s, the California Legislature attempted to limit African American migration into the state with unsuccessful anti-immigration bills introduced in 1851, 1855, and 1858.

Alabama attorney Solomon Heydenfeldt (1816–1890) wrote a controversial opinion about the impact of slavery on the Southern economy, “A Communication on the Subject of Slave Immigration,” in 1849. He opposed the immigration of slaves to Alabama, not as an abolitionist but as a pragmatist who viewed slave labor as unproductive because it inhibited industrialization. Heydenfeldt's minority view made him very unpopular; he was compelled to leave his home state and arrived in San Francisco in 1850, where he joined the law firm of Shafter, Shafter, Park and Heydenfeldt. Two years later, Heydenfeldt was the first Jewish person elected to serve on the California Supreme Court by a popular vote.

The adage “out of sight, out of mind” goes to the core of California economics that pushed ethical boundaries in the absence of oversight from the federal level; on this frontier, industry was slow coming. Those who speculated on land also speculated on maritime futures, essentially wagering on whether cargo would make it to destinations on time and complete—because mariners were abandoning ships to go to the goldfields. To keep commerce moving, local governments and leading commission merchants turned a blind eye to an emerging shanghai industry operating along the Pacific Coast. Any man would walk into a bar and be offered liquor or cigars laced with narcotics to induce a dozen hours of sleep—just long enough to find himself thrust into involuntary servitude on the high seas.

In this predatory ecosystem, women provided practical domestic industries cheaper than white men, but not men of color. The California Legislature passed “an Act to authorize married women to transact business in their own name as sole traders” on April 12, 1852. Married women could earn money for domestic tasks with limited guidance or control from husbands. This Act was not intended to give women financial independence within marriage but rather to bring a temporary infusion of domesticity to the wild economic winds of speculation that brought misfortune to California communities. Married women registered business plans, allowing husbands to formally invest and shelter up to \$5,000 in their enterprises. Women then developed properties on landfill acreage along a waterfront reconfigured with the latest technology, a waterfront that is now in the heart of San Francisco’s business district, and Heydenfeldt’s opinions would expand married women’s property rights.

Civic leaders believed they were carving out a just and rational order out of the chaos of America’s last frontier. Elected by miners with a working-class political agenda, delegates to the first California Constitutional Convention (1849) many quickly discerned that race was integral to the miners’ egalitarianism. West Coast workers converted this rhetoric into a potent political platform. San Franciscans established their own Mechanics’ Institute in 1854 as work in the goldfields slowed and advances in mining technology required more advanced partnerships. The Mechanics’

Institute was considered to be a landmark in California technical training until the University of California was established in 1868. Freeborn entrepreneur of African ancestry Mifflin Wistar Gibbs (1823–1915), who obtained an education from the Mechanics’ Institute, became a respected businessman in Gold Rush San Francisco and was among the signers on a petition opposing a ban on blacks testifying against whites. He was among the founders of the first formal African American political action group in California, known as the Franchise League of San Francisco.

“Fast Food” for a Mobile Population

During the War of 1812, the concept of canned food had been introduced in the United States. New Yorker Robert Ayars established the first American canning factory in 1812, using improved tin-plated wrought-iron cans for preserving oysters, meats, fruits, and vegetables. Demand for canned food greatly increased during wars—especially during the Civil War—when working-class men on the front were introduced to canned food. Canning companies expanded their businesses beyond military demands for nonperishable food, selling it to wider civilian markets after wars ended.

Inspired by the California Gold Rush, Gail Borden III (1801–1874) experimented with the idea of producing a dehydrated beef product known as the “meat biscuit,” which was loosely based upon a traditional Native American food called pemmican. Pioneers needed a readily transportable food source that could endure harsh conditions, and Borden marketed the meat biscuit to miners as a suitable solution. Borden invented condensed milk in 1856—cow’s milk from which water is removed and to which sugar is added, yielding a very thick, sweet product that can last for years without refrigeration if unopened. Soldiers used condensed milk during the American Civil War.

John Landis Mason (1832–1902) invented a reusable square-shouldered jar in 1858, which had a threaded screw top, matching lid, and rubber ring for an airtight seal. Before refrigeration and hothouse gardens, many fruits and vegetables had been available only seasonally, but the development of these jars made canning a practical alternative to drying, pickling, or

smoking to preserve food. Prior to Mason's innovation, preserving food in jars—under a layer of wax—had been messy, unreliable, and unsafe.

California gold would finance the Union during the Civil War. The war brought about new technologies: chief gunsmith and designer for Oliver Fisher Winchester's arms company, Benjamin Tyler Henry (1821–1898), adapted a breech-loading rifle in 1860 first designed by Walter Hunt. Union soldiers in the Civil War made the Henry rifle as famous as the Winchester. A movement toward "portability" shaped the business of war, and new gimmicks were developed to sell merchandise.

William Bullock (1813–1867) invented the rotary printing press in 1865; it could feed paper on a continuous roll and print both sides of the paper at once. Richard Gatling (1818–1903) had earlier patented a number of inventions, including a screw propeller (1839), a wheat drill-planting device (1839), and a steam-plow tractor (1857). While the introduction of Gatling's planting machines revolutionized the agricultural system in the United States, during the Civil War, he developed a gun based upon his seed planter that became the earliest precursor to the machine gun.

In science, demography (the study of human populations, including size, growth, density, distribution, and vital statistics), ecology (the science of relationships between organisms and their environments), and economics (the science of production, development, and management of material wealth) became interconnected. The evolution of science within such a context would eventually reduce the autonomy of scientists, who would become dependent upon institutions that could offer substantial capital investments for researching and developing ideas. After the Civil War, the professional scientist would become the innovator of ideas, concepts, and sensibilities. While scientists generate creative ideas that become the basis of innovations, not all of them are scientific leaders like Thomas Alva Edison (1847–1931), who would go beyond devising a commercially viable electric lightbulb—he also developed a utility for distributing electricity itself.

Adhesive Tape

Adhesive tape is a roll of backing material coated with a form of adhesive, used for sticking different objects together. Different backing materials and adhesives are used depending on the use of the tape.

Adhesives are substances that can hold two materials together. Usually adhesives are permanent. Natural adhesives include beeswax, resin, and bitumen. Ancient Egyptians used adhesives made from animal skin and bones. Medieval monks used egg white to bind gold leaf to their manuscripts. In the 19th century, rubber became a popular adhesive.

The first adhesive tape was made in 1845 by London surgeon Dr. Horace Day, who used a rubber

adhesive applied to strips of fabric to pioneer surgical tape. In 1882, a German pharmacist named Paul Beiersdorf invented an adhesive bandage. The next real advances in adhesive technology came in the 20th century, when synthetic materials were industrialized.

Perhaps the most famous adhesive tape/bandage was invented in 1921 by Earle Dickson, who improved on Horace Day's surgical tape by applying a piece of gauze to a cloth-backed tape and covering it with crinoline, creating what is now well known as the Band-Aid. The Band-Aid was created because Earle Dickson's wife, Josephine, frequently cut herself during cooking. The prototype Band-Aid allowed her to dress her wounds.

In 1923, Richard Drew created the world's first masking tape to help auto painters working in an auto body shop make clean dividing lines on a two-color paint job. Drew would later create Scotch tape from the same masking tape used in the auto shops. Scotch tape was named after Drew's Scottish boss from back when he worked for the 3M Company.

In 1942, the Revolite division of the Johnson & Johnson Company invented duct tape. During World War II, the troops needed a waterproof tape that was durable and useful for repairs: Johnson & Johnson coated a roll of cloth tape with polyethylene.

In the 21st century, there is a multitude of different types of adhesive tape made for different uses. Duct tape continues to be useful for taping air-conditioning ducts due to its durability and long life, but millions of Americans have a variety of uses for it. Gaffer tape is designed for film and camera production to temporarily hold things in place. Its adhesive is more resistant to heat and more easily removed without damaging surfaces. Packing tape used for postage is lighter and, therefore, cheaper. It tends to be thin and strong, but the adhesive only has to resist pulling sideways (a.k.a. "shear load"). Masking tape helps artists and painters, stopping paint from leaking under it and coming off cleanly afterward. Here, the strength of the adhesive and tape are much less important. Electrical tape must be a good insulator against electricity and should have a long life.

Making wallets out of duct tape became a trend in and around 2011, with Keith Drone of Nashville, Tennessee, claiming to be the father of the fad. Adhesive tape came out in 1845, when Doctor Horace Day invented it as a way to bandage surgical patients. Today surgeons use a form of super glue instead. Agassiz, Louis (1807–1873)

Louis Agassiz was a Swiss-born American naturalist and geologist. Known for his research on extinct fishes and glacier activity, Agassiz was a professor of zoology and geology at Harvard University and served as founding director of Harvard's Museum of Comparative Zoology. He was a staunch opponent of Darwin's theory of evolution.

John Louis Rudolph Agassiz was born in 1807 in Môtiers, Switzerland, to Rodolphe Agassiz, a Protestant minister, and Rose Mayor. As a young man, he studied at the universities of Heidelberg, Munich, and Erlangen, earning a PhD in 1829 and an MD in 1830.

His mentors included French comparative anatomist Georges Cuvier, a proponent of the idea that the extinction of species was a fact. In 1832, with the patronage of geographer Alexander von Humboldt, Agassiz was appointed a professor at the College of Neuchâtel. The following year, he married Cécile Braun, with whom he had three children.

Between 1833 and 1843, Agassiz published a series of studies called *Poissons fossiles*, a comprehensive exploration of more than 1,700 prehistoric fishes. This pioneering work established Agassiz's reputation in the scholarly community and suggested that intelligent design led to the creation of multiple, distinct species. In 1837, Agassiz was the first scientist to apply glacial theory to all of Europe, expanding ideas first suggested by Swiss naturalist Jean de Charpentier. His *Études sur les glaciers* (1840) and *Système glaciaire* (1847) became important works in the study of the ice age in Earth's northern hemisphere.

In 1846, Agassiz sailed alone to the United States to study the flora and fauna of the Americas. He spent the winter of 1846–1847 in Boston, lecturing at the Lowell Institute, and was then offered a three-year appointment as a professor of zoology and geology at Harvard's Lawrence Scientific School in 1847. After Cécile's death from tuberculosis in 1848, Agassiz decided to remain in Boston. In 1850, he married Elizabeth Cabot Carey, an intelligent and well-connected Bostonian. She was an ardent promoter of women's education, and she operated a school for young women at the Agassiz home from 1855 to 1863.

Agassiz encouraged Harvard to establish a natural history museum that could serve to educate the public and train graduate students. The Museum of Comparative Zoology opened in November 1859. Agassiz continued to search for new species to fill his museum, as well as creatures that would provide evidence of creationism. In 1865–1866, Louis and Elizabeth traveled to Brazil as part of an expedition funded by Boston banker Nathaniel Thayer. They collected over 34,000 species for the museum and authored a popular account of their voyage, *A Journey in Brazil*, in 1868.

Agassiz's reputation suffered toward the end of his career as he continued to promote creationism over Darwin's theory of evolution. He supported the view that different races of humans were different species, which lent credibility to those promoting scientific racism and sexism, although Agassiz did not support racial or gender inequality. Agassiz passed away on December 14, 1873.

Primary Document: Excerpt from the Journal of Louis Agassiz Describing a Trip to the United States (1846)

In 1846, Louis Agassiz, who divided much of his life between the United States and Europe, left Paris and traveled to the United States. The following is an excerpt from his journal, wherein he describes his American experience.

BOSTON, December, 1846.

Having no time to write out a complete account of my journey of last month, I will only transcribe for you some fugitive notes scribbled along the road in

stages or railroad carriages. They bear the stamp of hurry and constant interruption.

Leaving Boston the 16th of October, I went by railroad to New Haven, passing through Springfield. The rapidity of the locomotion is frightful to those who are unused to it, but you adapt yourself to the speed, and soon become, like all the rest of the world, impatient of the slightest delay. I well understand that an antipathy for this mode of travel is possible. There is something infernal in the irresistible power of steam,

carrying such heavy masses along with the swiftness of lightning. The habits growing out of continued contact with railroads, and the influence they exert on a portion of the community, are far from agreeable until one is familiar with them. You would cry out in dismay did you see your baggage flung about pell-mell like logs of wood, trunks, chests, traveling-bags, hat-boxes, all in the same mill, and if here and there something goes to pieces no one is astonished; never mind! we go fast,—we gain time,—that is the essential thing.

The manners of the country differ so greatly from ours that it seems to me impossible to form a just estimate regarding them, or, indeed, to pronounce judgment at all upon a population so active and mobile as that of the Northern States of the Union, without having lived among them for a long time. I do not therefore attempt any such estimate. I can only say that the educated Americans are very accessible and very pleasant. They are obliging to the utmost degree; indeed, their cordiality toward strangers exceeds any that I have met elsewhere. I might even add that if I could complain of anything it would be of an excess, rather than a lack, of attention. I have often found it difficult to make it understood that the hotel, where I can work at my ease, suits me better than the proffered hospitality . . .

But what a country is this! all along the road between Boston and Springfield are ancient moraines and polished rocks. No one who had seen them upon the track of our present glaciers could hesitate as to the real agency by which all these erratic masses, literally covering the country, have been transported. I have had the pleasure of converting already several of the most distinguished American geologists to my way of thinking; among others, Professor Rogers, who will deliver a public lecture upon the subject next Tuesday before a large audience.

A characteristic feature of American life is to be found in the frequent public meetings where addresses are delivered. Shortly after my arrival in Boston I was present at a meeting of some three thousand workmen, foremen of workshops, clerks, and the like. No meeting could have been more respectable and well-conducted. All were neatly dressed; even the simplest laborer had a clean shirt. It was a strange sight to see such an assemblage, brought

together for the purpose of forming a library, and listening attentively in perfect quiet for two hours to an address on the advantages of education, of reading, and the means of employing usefully the leisure moments of a workman's life. The most eminent men vie with each other in instructing and forming the education of the population at large. I have not yet seen a man out of employment or a beggar, except in New York, which is a sink for the emptyings of Europe. Yet do not think that I forget the advantages of our old civilization. Far from it. I feel more than ever the value of a past which belongs to you and in which you have grown up. Generations must pass before America will have the collections of art and science which adorn our cities, or the establishments for public instruction, sanctuaries as it were, consecrated by the devotion of those who give themselves wholly to study. Here all the world works to gain a livelihood or to make a fortune. Few establishments (of learning) are old enough, or have taken sufficiently deep root in the habits of the people, to be safe from innovation; very few institutions offer a combination of studies such as, in its ensemble, meets the demands of modern civilization. All is done by the single efforts of individuals or of corporations, too often guided by the needs of the moment. Thus American science lacks the scope which is characteristic of higher instruction in our old Europe. Objects of art are curiosities but little appreciated and usually still less understood. On the other hand, the whole population shares in the advanced education provided for all . . . From Springfield the railroad follows the course of the Connecticut as far as Hartford, turning then directly toward the sea-coast. The valley strikingly resembles that of the Rhine between Carlsruhe and Heidelberg. The same rock, the same aspect of country, and gres bigarre* (*Trias.) everywhere. The forest reminds one of Odenwald and of Baden-Baden. Nearer the coast are cones of basalt like those of Brissac and the Kaiserstuhl. The erratic phenomena are also very marked in this region; polished rocks everywhere, magnificent furrows on the sandstone and on the basalt, and parallel moraines defining themselves like ramparts upon the plain.

Anesthesia

Anesthesia is a state of mind and body marked by unconsciousness, loss of memory, relaxation of the muscles, and absence of pain sensation. Many substances are capable of rendering part or all of the symptoms associated with anesthetics; however, the modern “general anesthesia” delivered by inhalation or injection can be traced to the middle of the 19th century. Anesthetics are commonly used as an aid in medical procedures and are intended to render the patient calm and unresponsive before, during, and after a surgical procedure rather than exerting any direct medicinal or curative power. Those who study and practice the administration of anesthetics are anesthesiologists, and their field is anesthesiology—an important area in modern surgery.

Broadly construed, there are three types of anesthesia: general, dissociative, and regional. General anesthesia suppresses the central nervous system, causing lack of consciousness and sensation. A dissociative anesthetic (commonly called a sedative) inhibits nerve function and long-term memory but allows the patient to remain conscious. Finally, a regional anesthetic blocks the receptors of a particular part of the body from the rest of the nervous system. Each of these three varieties has applications for general medicine, surgery, dentistry, and therapeutics, among other disciplines.

There were attempts to discover a general anesthetic among the ancient Egyptians, Greeks, and Romans, as well as the Chinese. The surgical use of alcohol, opium, carbon monoxide, and even ice were all proposed with subjective criteria for success. It is largely agreed that two major breakthroughs of the late 18th and early 19th centuries made the advent of modern anesthetics feasible. British polymath Joseph Priestley’s experiments isolating nitrous oxide and other gases led to greater interest in “inhalable gases” as therapeutic options during the late 18th century. Further, in 1804, German pharmacist Friedrich Sertürner derived morphine from the opium poppy, isolating its powerful, addictive sedative.

News of these European discoveries was widely disseminated among academics in the United States, who witnessed the recreational “ether frolics” performed

by traveling purveyors to members of their audience for the amusement and edification of onlookers. In 1842, William Edward Clarke and William T. G. Morton, both undergraduates at Berkshire Medical College in Vermont, used ether as part of a dental extraction. Later that year, Crawford W. Long, a pharmacist and physician in Jefferson, Georgia, used ether when removing a tumor from the neck of a man named James Venable. While both of these occurrences demonstrate the interest that a rising generation of medical students took in general anesthetics, neither man chose to immediately publicize his actions.

Anesthesia continued to be used sporadically and experimentally by individual American practitioners. In 1844, Horace Wells, a Connecticut dentist, had a tooth removed with nitrous oxide by fellow dentist Gardner Quincy Colton. William T. G. Morton was at that time a business associate of Wells, and he arranged for his partner to publicly demonstrate his procedure at the Massachusetts General Hospital in Boston. This demonstration failed when the patient cried out in pain halfway through the procedure, and it failed to make the public relations impact that Morton desired.

Morton would be the first to successfully and publicly demonstrate the administration of general anesthetic during a surgery on October 16, 1846, in the posthumously titled “Ether Dome” operating theater of the Massachusetts General Hospital. Morton administered the anesthesia while Harvard doctor John Collins Warren removed a tumor from a patient. After the surgery was completed, Warren reportedly said, “Gentlemen, this is no humbug!” His demonstration was celebrated in the painting *First Operation under Ether* by Robert C. Hinckley, and other procedures were shown through the emerging medium of photography as a milestone in American medicine. Charles Thomas Jackson, a professor at Harvard University, later claimed that Morton had stolen the concept from him. Crawford Long, whose work in Georgia went unnoticed, also contested Morton’s claim as far as the floor of the U.S. Senate. These disputes lasted for the entire lifetime of the participants and have not been satisfactorily resolved even to this day. Massachusetts General Hospital continues to celebrate “Ether Day” in commemoration of Warren and Morton’s public demonstration.

Starting in the 1850s, chloroform (an organic compound derived from marine seaweed) gained in popularity as an anesthetic over ether both in the United States and Europe. This pattern was reversed in favor of ether once again after chloroform was found to have adverse cardiac health effects. Anesthetics gained steady acceptance among the medical community; however, specialization in administering it was not common until the 20th century. The first department of anesthetics was not established in the United States until 1936, when one was formed at the Massachusetts General Hospital.

At the turn of the 20th century, the majority of surgical anesthetics were inhaled, applied locally, or given intravenously (injected directly into the veins). These methods were not suitable for some surgical procedures, as there remained a great risk of blood and mucus buildup, which could threaten breathing. In 1913, American physician Henry Janeway developed tracheal intubation (the placement of a tube inside the air passage of a patient) and combined it with an inhaled anesthetic. Intratracheal anesthesia became commonplace in American hospitals and continued to develop during the 20th century. By the 21st century, small cameras could be used to maneuver the tube into place.

The first intravenous anesthetic, sodium thiopental, was created by Ernest H. Volwiler in 1934 at Chicago's Abbott Laboratories. At the time, lab scientists were busy finding a substitute for morphine-based anesthetics, which had dangerous addictive properties. The discovery of meperidine in 1939 and methadone in 1947 provided viable alternatives that possessed the same pharmacological benefits as traditional morphine derivatives.

New anesthetics and technologies continue to develop into the 21st century as surgical procedures become more intricate and specialized, while new alternatives to traditional anesthetics continue to be developed to respond to new needs and health care environments. Once prohibitively expensive, xenon gas has become a viable option because of advances in distribution technology and recycling.

Ball Bearings and Babbitt Metal

Ball bearings are simple components that allow mechanisms with rotating parts to move freely and with little friction. The common ball bearing is constructed from two rings and a number of small metal balls; thus the name “ball bearing.” One ring is large enough to contain the second ring with space in between, and the space is filled with the bearing balls. The balls allow the top ring to move around the bottom ring, with the only friction being from the small space where each ball touches the rings. The ball bearing is limited in strength only by what the small bearing balls can withstand while still fulfilling their function—which is why the alloys that make bearing balls, called “Babbitt metals,” are so important.

Babbitt metal is a kind of soft metal that wears easily, with an inner structure of hard crystals. The softer metal can therefore wear away and make paths for a bearing to pick up lubricants. Babbitt metals are resistant to “galling,” which is when material from one metallic surface becomes friction welded to another, causing tearing of the crystal structure as well as buildup that leads to additional wear. Most Babbitt metals are alloys of tin or lead, with tin alloys being more common in systems such as automotive engines. Lead bearings are used where constant turning motion is present, such as with saw blades. The tin in Babbitt alloys melts partially, protecting the bearing in situations where there is no lubricant. Because lead-based alloys tend to work harden, Babbitt metals made from lead can develop cracks.

Isaac Babbitt, who developed the first Babbitt metal, was born on July 26, 1799, in Taunton,

Ball bearings, seen here in production at the SKF Industries factory, are used to reduce rotational friction and support radial and axial loads. (Lofman/Pix Inc./The LIFE Images Collection/Getty Images)

Massachusetts. He trained as a goldsmith and was responsible for creating the first Britannia ware in the United States, a specific type of pewter alloy, popular due to its silvery smooth surface. He partnered with William Ware Crossman to form Babbitt & Crossman in May 1824. He worked for the South Boston Iron Company as a superintendent and was also responsible for creating the first brass cannon in the United States. In 1839, he created the first Babbitt metal, an alloy of copper and antimony in a soft mixture of tin. The patent for his metal states that it is for “a new and improved mode of making or constructing [machinery bearings] . . . by which . . . the heating and abrasion which are apt to occur . . . are prevented.” Congress

awarded him \$20,000 by for the invention. Thereafter, he manufactured his alloy as well as soap. He died on May 26, 1862, in Somerville, Massachusetts.

Best Friend Steam Engine

Some scholars call *The Best Friend of Charleston* the first locomotive built in America; other historians qualify the statement by saying it was the first locomotive built for sale to a railroad, to distinguish it from some earlier ones built by experimenters and designers.

In 1830, the South Carolina Canal and Rail Road Company, which had been chartered to build a line from Charleston to Hamburg, South Carolina, on the Savannah River, ordered a steam locomotive from the West Point Foundry in New York State. The railroad had hired one of America's leading steam locomotive experts, Horatio Allen (1802–1889), to aid in the design of this locomotive. When finished, the locomotive, which cost \$4000, was shipped by boat, disassembled, and delivered to Charleston on October 23, 1830. Personnel of the railroad assembled and tested it. In the early days of American railroading, locomotives were often given names, and this engine was christened *The Best Friend of Charleston* because local businessmen believed it would help boost commerce in the region.

On Christmas Day, 1830, *The Best Friend* pulled a two-car passenger train over six miles of track. Since the excursion had been announced in a newspaper the previous day, this was the first scheduled passenger train operation in the United States. A report in a Charleston newspaper later said that the train “annihilated time and distance” by travelling at what was then the remarkable speed of 15 to 25 miles per hour.

Unlike what most people likely think of as a typical locomotive, which has a long, horizontal boiler parallel to the track, *The Best Friend* had a vertical boiler. The steam it produced powered two cylinders that turned a crank, transferring power to all four wheels. Thus, all four wheels were powered drivers, and while the locomotive was diminutive, these wheels stood four and a half feet tall. The locomotive weighed about four and a half tons and ran on a five-foot track gauge. Gauges wider than the standard gauge in use today (which is four feet, eight and a half inches) were common in the early days of American railroading. Like many early locomotives, it had no cab to protect the engineer and fireman from the elements.

While it operated successfully in regular service for about six months, *The Best Friend* came to an early

and tragic end. On June 17, 1831, a fireman tied down the safety valve, which was designed to allow excess steam to escape safely. He might have done this to stop the noise the valve produced, or perhaps he believed that disabling it would give the locomotive more power. The result was the first locomotive boiler explosion in the United States, which killed the fireman—making it also the first recorded railroad accident in America with a fatality. For a time, when operating passenger trains with other locomotives, the South Carolina Railroad placed a flatcar loaded with cotton bales between the locomotive and the first passenger car in an attempt to allay passengers' fear of harm from a boiler explosion. Within three years, the South Carolina Railroad was operating six locomotives, and when its line was completed to the Savannah River in 1833, it was, at 136 miles, the longest railroad in the world.

A few years later, parts of *The Best Friend* were used to build a new locomotive in the South Carolina Railroad's shops. This locomotive was named *The Phoenix*, and it continued in service until shortly before the Civil War. The South Carolina Railroad was eventually absorbed into the Southern Railway, and in 1928, the Southern built an operable replica of *The Best Friend* to commemorate the centennial of the building of the South Carolina Railroad.

Today, the Southern Railway is part of the Norfolk Southern Railway, and in the early 2000s, the Norfolk Southern refurbished *The Best Friend* at the railroad's shops in Chattanooga, Tennessee. Today, this replica is at the Best Friend of Charleston Museum in Charleston, South Carolina. Another replica can be seen at the South Carolina State Museum in the state's capitol city, Columbia.

Breast Pump

On June 20, 1854, the U.S. Patent Office issued Patent No. 11,135 to Orwell H. Needham, a physician and inventor in New York, for a breast pump that used vacuum technology to help women express breast milk. Needham's creation was an improvement over earlier machines. He had devised an apparatus that used tubing to connect a small, hand-pumped bellows to a flexible nipple shield rather than directly to a glass container.

Women have been using breast pumps to trigger the milk ejection response for centuries. The ancient Greeks used *guttus*—ceramic vessels with long necks and spouts—to both empty the breast and feed the infant a few drops at a time. The Romans used glass milk extractors, which were sucked by the mother herself. The first published evidence of the use of a glass implement for evacuating breast milk appears in a pediatrics textbook published in 1577 by Omnibonus Ferrarius. An illustration in the text shows a small, globular glass container widened at the lip and attached to a glass pipe at its base. The lip was placed over a woman's nipple, and the tip of the pipe was placed in her mouth. As she drew on the pipe, air was pulled from the apparatus, and the resulting suction triggered the expression of milk, which collected in the glass reservoir. Also called a sucking glass, the contraption was recommended as a method for reducing engorgement when a breast was not completely emptied. This model did not change much until the mid-19th century.

Needham's pump was the first of several improved devices that resemble modern human breast pumps. Recognizing that placing glass directly over the nipple could be painful, his model proposed the use of a nipple shield composed of India rubber that could fit snugly over the breast when suction was employed using a bellows. Needham's pump was designed to be hand operated, whereby a mother squeezed the bellows in a repetitive fashion, allowing her to control the pressure and frequency of milk expression. Small manual pumps proved inefficient, however, requiring significant effort on the part of the user and allowing for only one breast to be pumped at a time. These devices also failed to remove all of the milk from the breast.

The next important innovation came in the form of machine-driven suction. In the early 1920s, Edward Lasker created a mechanical breast pump that provided

intermittent sucking action imitating that of an infant. The pump was designed to create a massaging effect that would stimulate milk production. It was not until 1991 that Medela, a Swiss company, introduced the first nonhospital, electric-powered, vacuum-operated breast pump in the United States. Today's pumps allow women to extract their milk rapidly using a double pump, and to continue to express their milk for weeks or even months.

Brown Truss

Invented by Josiah Brown Jr., the box truss became known more colloquially as a Brown truss. It was most often used in covered bridges and protected from the elements with outside sheathing. The Brown truss was designed with two-force members assembled such that the separate pieces work together as a single object. In this way, force is applied to only two points, making the structure more sound and capable of supporting more weight.

Brown described the way his truss would work in his 1857 patent application when he wrote, "when the timbers of the chords are brought together they are combined and become, as it were, only one piece, no part of which can be operated upon or affected independently of the other by the downward and upward thrusts common to truss bridges."

Further, by arranging stiff panels in a cylindrical shape, the Brown truss had a higher resistance to twisting along its long axis and a higher resistance to buckling than a simple truss. Many types of trusses existed and had been in service before Brown's invention, including the geodesic dome, a truss in the shape of a sphere.

Burglar Alarm

The first electromagnetic burglar alarm was invented by the Unitarian pastor Augustus Russell Pope (1819–1858) of Somerville, Massachusetts.

A Harvard graduate, Pope was an eloquent lecturer and a man of many interests, among them physics and mechanics, and the patent for his invention was granted on June 21, 1853 (U.S. Patent 9,802). Pope's design used a battery, magnets, and a bell as individual units mounted on each window or door. While a door is closed (or a window sash is down), the magnetic circuit is broken because the spring of the key is thrown out of connection with the upper wire of the door (or window frame), but as soon as the door or window is opened, the spring of the key comes into contact with the wire, closing the circuit. The electrical current flows through the circuit breaker, charging the magnet and drawing the hammer toward the bell, causing the bell to ring.

Pope installed the alarm in his own home and several other houses. He attempted to market his invention in the local newspapers, but the public was reluctant to embrace it. He even presented his invention at the Fair of the Mechanics Charitable Association in Boston in 1856, but it did not draw prospective customers and was never put into mass production, because the general public still mistrusted electricity and associated it with danger and even death.

In 1858, Pope sold and transferred the rights to his invention for \$8,000 in notes and \$1,500 in cash to Edwin Holmes of Boston, an entrepreneurial shopkeeper turned businessman who set up a company to install and operate electric burglar alarm systems in that city. Business took off a year later, after the Holmes Burglar Alarm Company moved to New York (where, so the company slogan said, "all the country's burglars made their home"). New York proved ideal for the business because the city had electrified and the public began warming up to the idea of electrically powered devices. Holmes proactively publicized his

product and made some improvements himself, which increased its popularity. By 1866, the number of his customers had reached 1,200.

Holmes's son, Edwin Thomas Holmes, also played an active role in the company and was in charge of operations in Boston, where the company had 700 customers. In Boston, Edwin decided to use preexisting phone cables instead of laying new ones dedicated for alarm use only. Other improvements included the use of one centralized bell (usually in the owner's bedroom) instead of separate bells on every door and window, the use of a clock to turn the alarm on and off, the introduction of zones, and building a network of alarms to be monitored by a central office. In 1905, the American Telephone and Telegraph Company purchased the Holmes Electric Protective Company and linked it to the police-and-firefighting emergency call system: the burglar alarm industry was born.

Calliope (Steam Organ)

The steam calliope, also known as the steam organ or steam piano, was patented by Joshua C. Stoddard in 1855. Originally designed as a replacement for church bells, the steam calliope became a popular attraction at circuses and on riverboats in the 19th century.

The calliope consists of a series of tuned steam trumpets or whistles that produce musical notes when steam is sent through them. Stoddard's original calliope consisted of 15 whistles that were attached to a small steam boiler and utilized roller-and-pin technology that was common in music boxes of the day. A revolving spoked cylinder opened and closed valves

Invented by Joshua Stoddard, a beekeeper from Massachusetts, the Calliope steam organ worked by forcing steam through a group of large whistles. The piano-player technology of the early 20th century replaced the calliope's human operator with a music roll. (Bettmann/Getty Images)

that controlled the flow of steam. Stoddard later replaced the cylinder with a keyboard so that the instrument could be played like a piano. The whistles were tuned to a chromatic scale, but it was difficult to keep a calliope in tune due to the fluctuating temperature of the steam. Early whistles were made of cast brass and often produced harsh and off-pitch notes. Beginning in 1890, the calliope manufacturer Thomas J. Nichol used sheet copper for the bells of the whistles to produce a "sweeter" sound.

The steam calliope with a keyboard debuted July 4, 1855, in Worcester, Massachusetts. Stoddard controlled the steam while his daughter played "Yankee Doodle." He patented this calliope that year and founded the American Steam Piano Company. Spaulding and Rogers Circus first introduced the calliope to their circus showboat, *The Floating Palace*. Steamboats supplied the required steam from their boilers, and calliopes were also installed in steam-driven carousels. In 1870, P. T. Barnum was so

impressed with the calliope that he had one installed in a circus wagon in hopes that it would draw crowds to his circus. It is said that Barnum renamed the steam organ "the calliope" after the Greek goddess of that name (which means "beautiful voice"). Although closely associated with circuses and circus wagons, calliopes were commonplace on steamboats after the Civil War.

Around 1900, manufacturers began to produce calliopes that used music rolls, much like a player piano. But the keyboard remained, allowing someone to play the instrument manually. It was during this time that compressed air began to replace steam in the instrument, making it safer and more convenient. The Tangley Calliaphone, a 43-whistle calliope, used compressed air and could play type A piano rolls. These popular calliopes could be played automatically or manually and were small enough to be mounted on wagons or automobiles. They were used as advertising gimmicks in the early 20th century.

Calliopes have between 25 and 67 whistles, with most having 32. The largest steam calliope ever built was for the *Mississippi Queen*, built in 1975. The *Mississippi Queen* calliope has 44 gold-plated, solid brass pipes. In 1958, Richard Simonton and E. J. Quimby purchased a calliope that had been salvaged from the *Water Queen*. They electrified the keyboard and replaced each steam valve with a solenoid valve. In 1960, they installed the converted calliope on the *Delta Queen*. It was the first calliope with a remote keyboard. It allowed the calliopist to play the instrument away from the whistles themselves. In the 1970s, several new steamboats were being built and needed steam calliopes. Dave Morecraft restored and then replicated a Nichol circus calliope. His first calliope is privately owned, and the second was installed on the *Belle of Louisville*. In 1975, an exact replica of a hundred-year-old calliope was built for the steamboat the *Natchez*.

Joshua C. Stoddard received little compensation for his invention. His parents did not approve of his frivolous instrument, and the city of Worcester banned the calliope within the city limits because of the noise. One of his financial backers, Henry Deny, eventually ousted Stoddard from the American Steam Piano Company and took over as its president. Deny later claimed that he had invented the calliope. After he lost control of his company, Stoddard returned to farming and beekeeping. Although he patented several other inventions, none were successes.

Cannon, Double-Barrel

The double-barrel cannon was an American Civil War-era experimental weapon that never saw battle. The

concept of the double-barrel cannon was created in 1862 by dentist, builder, and mechanic John Gilleland, who raised money via a subscription fund from Confederate citizens in Athens, Georgia, to build the ultimate chain-shot gun for \$350. Now the double-barrel cannon is one of the most popular landmark attractions in that city.

The double-barrel cannon featured side-by-side bores (barrels). The concept meant that artillerymen would load two cannonballs, linked together by a 10-foot chain, into each barrel. The cannon would then be fired using one vent hole to light the fuse, with the fuse leading to both tracks of the cannon. However, this ambitious idea had a timing issue that caused one barrel to fire sooner than the other. The chain often snapped, causing the two cannonballs to go in different directions. During testing, the “Secret Weapon” effectively mowed down trees, tore up a cornfield, knocked down a chimney and killed an unfortunate cow. Eyewitness accounts described the test firing as catastrophic; the fired cannonballs took a circular motion, plowing up about an acre of ground, tearing up corn and mowing down saplings. The weapon never hit its designated target during testing. Yet its unfortunate results did not deter Gilleland from declaring the testing an unqualified success.

The cannon was then sent to the Confederate arsenal in Augusta, Georgia, for further testing. The commandant there, Col. George W. Rains, tested the weapon extensively and reported that it was not usable due to unpredictable rates of powder burn and barrel friction that led to unreliable performance. The cannon was then sent back to Athens, Georgia.

This enraged Gilleland, who wrote many stern letters corresponding with the Confederate secretary of war, James W. Camak, to the Confederate government in Richmond, Virginia. Despite Gilleland’s displeasure, the Confederate government never used the double-barrel cannon in battle.

The cannon was placed in front of the Athens town hall, to be used as a signal gun in case of attack by the United States Army. It remained there until August 2, 1864, when it was hauled out of town to the hills by Barber Creek to repel the approach of Brig. Gen. George Stoneman and his Union cavalry troops. Reports say that the cannon was loaded with canister shots, not balls.

After the war, this bold weapon was placed at the corner of College and Hancock Avenues in Athens, Georgia, where it remains today.

Hazlett, James C., M. Hume Parks, and Edwin Olmstead. 2004. *Field Artillery Weapons of the Civil War*. Urbana: University of Illinois Press.

Primary Document: Excerpt from the Memoirs of Former Confederate General Edward Porter Alexander on “Artillery Hell” at Antietam (1907)

Artillery was an important aspect of almost all Civil War battlefields. In the postwar years, the Battle of Antietam (also known as the Battle of Sharpsburg), fought in western Maryland on September 17, 1862, became particularly known for the devastating use of artillery on both sides. General Stephen D. Lee, a Confederate artilleryman, in a comment later recorded by General E. P. Alexander in the following passage from his 1907 memoirs, later remembered Antietam as “artillery hell.”

A strong feature of our centre was that the Antietam cut in half the ground over which the enemy must manoeuvre, and would more or less embarrass any infantry attack upon it; but, per contra, there were two ugly features: (1) The country is a rolling one and the hills near the stream are often quite steep, thus giving the enemy fairly close approach under cover. (2) Our whole line except the cavalry on the left was within range of the enemy’s rifle-guns planted along the high ridges east of the Antietam, beyond the effective range of our guns.

Thence, perfectly safe themselves, they practised upon us at leisure all day. Hunt, the Federal chief of artillery, describes the location of 10 heavy batteries of the reserve artillery, and says:—

They overlooked the enemy and swept most of the ground between them and our troops. They were well served, especially the guns of Benjamin’s battery. Their field of fire was extensive, and they were usefully employed all day and so constantly that the supply of ammunition for the 20-pounders ran short.

As to how our artillery fared in opposition, we may judge from a remark made to me two months later by Col. S. D. Lee, upon my being transferred to the artillery service: “Pray that you may never see another Sharpsburg. Sharpsburg was Artillery Hell.”

Civil War Medicine (1861–1865)

The Civil War is considered the United States’ first modern war. It was the first to take place after the Industrial Revolution, which had made the large-scale manufacturing of armaments and the use of modern transportation, such as railroads, possible.

While the impact of such large-scale wars on the populations involved is obvious, what is often not widely noted are the rapid advances made by medicine during such times, and the Civil War was the first American war to have its medical care thoroughly documented. While the improvements of that time may seem primitive by today’s standards, they set the

stage for a rapid advance of the overall quality of American medical practice.

As a result of what was learned in the war, the training of thousands of physicians was upgraded, and they were introduced to improved standards of care. These included advances in techniques for the prevention and treatment of infectious disease, improvement in surgical principles, and more rapid and systematic assessment of patients’ needs.

The Civil War resulted in the highest number of deaths of all the wars in which Americans have fought. A total of 620,000 men died: 360,000 in the North and 260,000 in the South, which was about a quarter of all who served. However, most of these men died from

illness, not injury. For every three soldiers killed in battle, five more died of disease. Typhoid fever was a leading killer, and diarrhea affected 74 percent of soldiers in any given year.

Those who were injured in battle faced their own unique set of problems. Medical care for the casualties from the first Battle of Bull Run in July 1861 was essentially nonexistent. There was no organized evacuation of these men, and no hospitals were available to handle their numbers. Those wounded who could evacuate themselves filled the streets of Washington, D.C., seeking shelter and treatment. Those who could not lay unattended on the battlefield, where they died of their injuries, thirst, or exposure.

The Union Army would come to rely on one very important ally whose focus was dedicated to the improvement of care—the United States Sanitary Commission (USSC).

At the start of the war in April 1861, there was an outpouring of support and concern by the public for the troops' welfare. A delegation of New York City's civic leaders and medical community went to Washington, D.C. to appeal to the federal government to form an aid group. The USSC was created by federal legislation on June 18, 1861, with its initial mission to support sick and wounded soldiers who had volunteered to fight (at the outbreak of the war, the regular U.S. Army consisted of only 16,200 men, far below the number that would be needed in the conflict). Later it would expand its service to regular army troops and sailors. Operating across the North, the USSC raised nearly \$25 million over the course of the war to support the cause, and enlisted thousands of aid volunteers.

Pressure from members of the USSC was responsible for the appointment of Surgeon General William Hammond in April 1862. He appointed an army medical director, Jonathan Letterman, who would become known as “the father of modern battlefield medicine.” These men initiated a series of reforms that would vastly improve the handling of the sick and wounded.

Hammond required medical officers to submit reports of their activities, treatments used, and their results. After the war, these records were collected into a six-volume set, the *Medical and Surgical History of the War of the Rebellion*, which was the first major American academic medical contribution

recognized in Europe. It provided detailed written and visual documentation of medical and surgical management during the war. These records allowed medical personnel to compare treatment approaches.

Another issue Hammond took up in 1862 was the lack of competence of army medical officers. Even those designated as surgeons frequently had little or no operative training, and a complete lack of knowledge regarding sanitation was common. Hammond developed a medical examination process to weed out those with inadequate training. He also developed a hospital inspection system to ensure adequate levels of cleanliness and care.

An intense hospital building program was started in 1862. By the end of the war, these hospitals were built in a pavilion style, which consisted of long, separate ward buildings with high, arched ceilings that allowed for greater ventilation. Patients with similar ailments were housed together. During the Crimean War, British nurse Florence Nightingale had demonstrated that this style of hospital, when combined with cleanliness, helped prevent the spread of illness. This design would be copied for large civilian hospitals for the following 75 years.

Nursing care was another issue. Initially, men from the ranks performed nursing chores. These were either sick soldiers who had recovered sufficiently to do the job, or those who had been sent from their regiments to work in the hospitals (the latter were often poor performers who had been dispatched simply to get rid of them). Women had served as nurses in a limited capacity during the Crimean War, but the Civil War would mark their first widespread use. Dorothea Dix, a teacher and advocate for the mentally ill, volunteered to put together a corps of female nurses. The women serving in Union hospitals would grow to 3,000 or 4,000 in number by the end of the war.

While Hammond worked on raising standards, Letterman devised a system of managing mass casualties, starting with aid stations set up immediately behind the scene of battle. Treatment at the aid stations consisted of controlling bleeding, bandaging wounds, and administering morphine and whiskey for pain. It was learned there that bleeding was best controlled by pressure dressings or by using stitches. The use of stitches and the associated skill developed in

applying them was one of the major advances in surgical technique of the time.

The next link in Letterman's system was the field hospital. From an aid station, soldiers could be taken via horse-drawn ambulances to these hospitals, which were within a mile or two of the battlefield.

Medical personnel learned that any definitive treatment of wounds should take place within 24 hours of the injury. The existence of bacteria and viruses and their role as causes of infection was not yet known, but it was recognized that when wounds were treated quickly, the patient was more likely to recover. It was at field hospitals that most surgeries took place.

The vast majority of battlefield wounds were caused by bullets, with the arms and legs most frequently affected, leading to amputation being the most common surgical procedure. While the mortality rate was high—about 25 percent of amputation patients died—the rapid treatment combined with the operative experience gained by surgeons meant that the death rate was much lower than for the same surgery in the civilian world: around 75 percent.

Anyone who required longer-term care could be sent to a general hospital in or near a major northern city. The availability of these general hospitals meant that field hospitals could be emptied rapidly if necessary, leaving them prepared for the next battle. This system would provide the basis for managing the wounded, from World War I until the Korean War.

It was in the general hospitals that wound infections such as gangrene were treated. Middleton Goldsmith, surgeon in chief of the military hospitals in Kentucky and Ohio, noted that patients whose rooms were deodorized with a spray containing bromine, an antiseptic related to chlorine, seemed to recover from gangrene more frequently. He developed a gangrene treatment in which the affected area was cleansed directly with a bromine solution. As a result, deaths

from gangrene fell from 60 percent to just 2.6 percent.

Another surgeon, William W. Keen, stopped a gangrene epidemic at his hospital in Philadelphia by isolating the affected patients, using fresh bandages on all wounds, dressing infected wounds last, and requiring cleanliness of all personnel, including that they had to wash hands between cases. This inspired an entirely new standard of care.

Advances were also made in reconstructive surgery. Eleven percent of battle wounds were to the face and neck and, as the war progressed, devastating injuries to the face were treated successfully, usually by stretching a flap of adjacent unaffected skin over the wound in a technique similar to what was done to cover the end of an amputated limb. After the war, additional surgeries to improve function and appearance were often conducted and the results recorded, providing a base for the development of modern plastic surgery.

As a result of what was learned because of the war, the general populace benefited from better-trained medical personnel, who were beginning to understand the value of sanitation and the importance of prompt treatment in better outcomes for their patients.

Primary Document: Report of Medical Director Robert Murray on Union Casualties Suffered at the Battle of Shiloh (1862)

In April 1862, Robert Murray was medical director for the military district Department of the Ohio and traveled to the Battle of Shiloh (April 6–7) with the

Army of the Ohio commanded by General Don Carlos Buell. At Shiloh, Buell's army reinforced General Ulysses S. Grant's Army of the Tennessee, which was

there heavily engaged with the Confederates. As the ranking medical officer on the field, Murray issued the following report on Union casualties at Shiloh on April 21, 1862. Shiloh, also known as the Battle of Pittsburgh Landing, was the deadliest battle of the Civil War up to that time, with almost 24,000 casualties between the two sides.

MEDICAL DIRECTOR'S OFFICE, ARMY OF THE OHIO,

Camp on Field of Shiloh, April 21, 1862.

SIR: I have the honor to submit the following report of the operations of the medical department during and after the battle of the 6th and 7th instant:

On the morning of the 6th I was at Savannah, and being ordered to remain at that place, I occupied myself in procuring all the hospital accommodation possible in that small village and in directing the preparation of bunks and other conveniences for wounded. In the afternoon the wounded were brought down in large numbers, and I then superintended their removal to hospitals, and did all in my power to provide for their comfort. On Sunday evening, the divisions being under orders to come up as rapidly as possible, I ordered the medical officers, as it was impossible to take their medical and hospital supplies—the teams and ambulances being in the rear and the roads blocked up with trains—to take their instruments and hospital knapsacks and such dressings and stimulants as could be carried on horseback, and to go on with their regiments. I left Savannah by the first boat on Monday, and arrived at Pittsburg Landing at about 10 a.m. I found the principal depot for wounded established at the small log building now used as a field post-office. They were coming in very rapidly, and very inadequate arrangements had been made for their reception. I found Brigade Surgeon Goldsmith endeavoring to make provision for them, and at his suggestion immediately saw General Grant, and obtained his order for a number of tents to be pitched about the log house.

I then rode to the front and reported to you. The great number of wounded which I saw being transported to the main depot, and the Almost insurmountable difficulties which I foresaw would exist in providing for them, convinced me that my presence was needed there more than at any other point on

the field. After spending an hour in riding a little to the rear of our lines, and seeing as far as possible that there were surgeons in position to attend immediately to the most urgent cases, I returned to the hill above the Landing, and used every exertion to provide for the wounded there. I ordered Brigade Surgeons Gross, Goldsmith, Johnson, and Gay to take charge of the different depots which were established in tents on the hills above the Landing, directing such regimental and contract surgeons as I could find to aid them. Many of the wounded were taken on board boats at the Landing and some of our surgeons were ordered on board to attend them. On Tuesday I had such boats as I could obtain possession of fitted up with such bed-sacks as were on hand and with straw and hay for the wounded to lie upon, and filled to their utmost capacity, and at once dispatched to convey the worst cases to the hospitals on the Ohio River, at Evansville, New Albany, Louisville, and Cincinnati. In removing the wounded we were aided by boats fitted up by sanitary commissions and soldiers' relief societies and sent to the battle-field to convey wounded to the hospitals. Some of these, especially those under the direction of the United States Sanitary Commission, were of great service. They were ready to receive all sick and wounded, without regard to States or even to politics, taking the wounded Confederates as willingly as our own. Others, especially those who came under the orders of Governors of States, were of little assistance, and caused much irregularity. Messages were sent to the regiments that a boat was at the Landing ready to take to their homes all wounded and sick from certain States. The men would crowd in numbers to the Landing, a few wounded, but mostly the sick and homesick. After the men had been enticed to the river and were lying in the mud in front of the boats it was determined in one instance by the Governor to take only the wounded, and this boat went off with a few wounded, leaving many very sick men to get back to their camps as they best could. By the end of the week after the battle all our wounded had been sent off, with but few exceptions of men who had been taken to camps of regiments in General Grant's army during the battle. These have since been found and provided for.

The division medical directors were very efficient in the discharge of their duties, and they report most

favorably of the energy and zeal displayed by the medical officers under them in the care of the wounded under most trying circumstances—of want of medical and hospital stores, and even tents. Owing to the fact that a large majority of the wounded brought in on Monday and Tuesday were from General Grant's army, some of whom had been wounded the day before, it was impossible to attend particularly to those from our own divisions. Many Confederate wounded also fell in our hands, and I am happy to say that our officers and men attended with equal assiduity to all. Indeed, our soldiers were more ready to wait on the wounded of the enemy than our own. I regret to say that they showed incredible apathy and repugnance to nursing or attending to the wants of their wounded comrades, but in the case of the Confederates this seemed in some measure overcome by a feeling of curiosity and a wish to be near them and converse with them.

We were poorly supplied with dressings and comforts for the wounded and with ambulances for their transportation, and it was several days after the battle before all could be brought in. Our principal difficulty, however, in providing for the wounded was in the utter impossibility to obtain proper details of men to nurse them and to cook and attend generally to their wants, and in the impossibility of getting a sufficient number of tents pitched, or in the confusion which prevailed during and after the battle to get hay

or straw as bedding for the wounded or to have it transported to the tents. The only details we could obtain were from the disorganized mob which lined the hills near the Landing, and who were utterly inert and inefficient. From the sad experience of this battle and the recollections of the sufferings of thousands of poor wounded soldiers crowded into tents on the wet ground, their wants partially attended to by an unwilling and forced detail of panic-stricken deserters from the battle-field, I am confirmed in the belief of the absolute necessity for a class of hospital attendants, enlisted as such, whose duties are distinct and exclusive as nurses and attendants for the sick, and also of a corps of medical purveyors, to act not only in supplying medicines, but as quartermasters for the medical department.

I append a list of the number of killed and wounded in each regiment, brigade, and division engaged, in all amounting to 236 killed and 1,728 wounded.

Very respectfully, your obedient servant,
R. MURRAY,
Surgeon, U. S. Army, Medical Director.
Col. J. B. FRY,
Asst. Adjt. Gen. and Chief of Staff, Army of Ohio.

Civil War Nursing

Motivated by patriotism, compassion, economic necessity, or obligation, both black and white women nursed sick and injured soldiers on both sides of the conflict during the American Civil War. Female nurses confronted class and gender biases by taking on hospital work, paving the way for nursing to become an acceptable profession for middle-class women in the late 19th century. The vast majority of nurses did not continue their hospital work after the war, but a few prominent women continued to administer hospitals, train nurses, and receive medical training.

Hannah Ropes (1809–1863), an abolitionist who worked at Union Hospital in Washington, D.C.,

explained her motivations to care for soldiers: “I am a mother, and I have only to remember that each of these sick ones [has] a mother somewhere, and for the time I act for them” (Brumgardt 1980, 89). Female nurses acted as surrogate mothers and sisters, reminding sick and wounded soldiers of home. While Americans associated comfort, feeding, and caring for the sick with appropriate women's roles, nursing strange men in a hospital challenged middle-class notions of respectability.

Union and Confederate records are incomplete, and calculations vary based on one's definition of “nurse,” but using a congressional study of hospital attendants compiled in 1890, Jane E. Schultz asserts that over 21,000 women nursed Union soldiers during

the war. Regardless of job title (cook, matron, or nurse), nearly all women attendants were involved in some aspect of patient care, delivering food, cleansing wounds, or changing linens. Even regimental laundresses often doubled as nurses, caring for sick soldiers or assisting the wounded on the battlefield. Fewer white women worked in Confederate hospitals, as the system relied heavily on slave labor. Using the appropriations for the Confederate Medical Department, Libra R. Hilde (2012) estimates that 1,666 women worked as hospital matrons in 1864, and in 1863, nearly half of the attendants in Georgia's 19 hospitals were enslaved. A few women, such as Clara Barton, tended soldiers on the battlefield, but most women nurses worked in urban areas far away from the fighting. Not all women accepted pay for their services, so actual numbers could be higher than these estimates.

The Confederate Army and the Union Army structured hospital work according to race and class. In 1861, U.S. secretary of war Simon Cameron appointed Dorothea L. Dix as superintendent of army nurses. An experienced activist for the mentally ill, Dix sought to manage the flood of volunteers who sought nursing positions. To avoid sexual innuendo and potential romantic attachments, Dix only approved applicants who were over age 30, were plain looking, and had certified recommendations from physicians and clergymen. Dix's requirements reflected a preference for hiring mature, respectable white women in positions of authority, but aspiring nurses often maneuvered around Dix's restrictions. In October 1863, disgruntled surgeons also undercut her authority when General Order No. 351 permitted the surgeon general to appoint nurses without Dix's approval. Louisa May Alcott managed to gain a nursing position at the Union Hotel Hospital in Washington, D.C. Her story illustrates the danger of volunteering as a nurse in that she contracted typhoid after three weeks and nearly died. Her first book, *Hospital Sketches*, was a collection of letters from her nursing service.

Confederate hospital matrons also tended to be mature white women, widowed or unmarried, from the middle or upper classes. They managed a hospital's domestic operations by securing and distributing food and supplies, overseeing the kitchen and laundry, and supervising hospital workers except physicians. In

both Union and Confederate hospitals, ward nurses cleaned wounds, changed bandages, applied poultices, changed bedpans and linens, scrubbed floors, fed patients, wrote letters (if literate), and visited with patients. Ward nurses included middle- and working-class white women, convalescent soldiers, and Catholic sisters. Black men and women tended to be assigned the most menial or difficult tasks in the wards, laundries, and kitchens. The U.S. and Confederate governments recognized the value of women's labor by paying them for their services. Although pay arrangements varied, Dix's nurses earned 40 cents per day, and head matrons in Confederate hospitals earned \$40 per month.

Approximately 600 sisters from 21 different religious communities nursed both Union and Confederate troops in hospitals, prisons, and transport ships between 1861 and 1865 (Maher 1989, 38, 70). Mary Denis Maher argues that the structure and training of their religious communities made Catholic sisters good fits for service in military hospitals. Communities with nursing experience, such as the Daughters of Charity, had the skills and discipline to work effectively with doctors and patients, manage supplies, and maintain the cleanliness of a hospital. Half of the sister-nurses who served during the war belonged to the Daughters of Charity, and 90 of them staffed Satterlee Hospital in Philadelphia, the largest Union hospital, which housed 7,000 patients after the Battle of Gettysburg. While sisters confronted anti-Catholic prejudices during the war, physicians generally appreciated their services. Reactions from other women nurses remained mixed. Some nurses and relief workers praised the sisters' efforts, but conflicts could emerge partly because the sisters insisted on maintaining a hospital environment where they could follow their religious community's rules and established procedures.

By working in a military hospital, women nurses from all backgrounds and income levels challenged 19th-century domestic ideology, which asserted that the proper place for middle-class women was in the home. While patients often appreciated their comforting presence, many physicians resisted women's involvement in hospital work. Convalescent soldiers understood their place in the military hierarchy, but middle- and upper-class nurses expected to be treated

as equals and often publicly criticized doctors' and surgeons' shortcomings.

Primary Document: Clara Barton's Poem "The Women Who Went to the Field" (1892)

In November 1892, Clara Barton read the following poem about Civil War nurses during a reception held at the Willard Hotel in Washington, D.C., for the Potomac Relief Corps, a unit of the National Woman's Relief Corps. Barton volunteered as a nurse during the Civil War, distributing supplies, cleaning hospitals, and nursing wounded and sick soldiers. Her nursing work during the war earned her the nickname "Angel of the Battlefield."

The Women Who Went to the Field
The women who went to the field, you say,
The women who went to the field; and pray,
What did they go for?—just to be in the way?—
They'd not know the difference betwixt work
and play,
What did they know about war, anyway?
What could they do?—of what use could they
be?
They would scream at the sight of a gun, don't
you see?
Just fancy them round where the bugle notes
play,
And the long roll is bidding us on to the fray.
Imagine their skirts 'mong artillery wheels,
And watch for their flutter as they flee 'cross
the fields
When the charge is rammed home and the fire
belches hot;—
They never will wait for the answering shot.
They would faint at the first drop of blood, in
their sight.
What fun for us boys,—(ere we enter the fight;)

They might pick some lint, and tear up some
sheets,
And make us some jellies, and send on their
sweets,
And knit some soft socks for Uncle Sam's
shoes,
And write us some letters, and tell us the
news.
And thus it was settled by common consent,
That husbands, or brothers, or whoever
went,
That the place for the women was in their own
homes,
There to patiently wait until victory comes.
But later, it chanced, just how no one knew,
That the lines slipped a bit, and some 'gan to
crowd through;
And they went,—where did they go?—Ah;
where did they not?
Show us the battle,—the field,—or the spot
Where the groans of the wounded rang out on
the air
That her ear caught it not, and her hand was
not there,
Who wiped the death sweat from the cold,
clammy brow,
And sent home the message;—"T is well with
him now"?
Who watched in the tents, whilst the fever
fires burned,
And the pain-tossing limbs in agony turned,
And wet the parched tongue, calmed deliri-
um's strife

Till the dying lips murmured, "My Mother,"
 "My Wife"!
 And who were they all?—They were many, my
 men:
 Their record was kept by no tabular pen:
 They exist in traditions from father to son.
 Who recalls, in dim memory, now here and
 there one.—
 A few names where writ, and by chance live
 to-day;
 But's a perishing record fast fading away.
 Of those we recall, there are scarcely a score,
 Dix, Dame, Bickerdyke,—Edson, Harvey and
 Moore,
 Fales, Wittenmeyer, Gilson, Safford and Lee,
 And poor Cutter dead in the sands of the sea;
 And Frances D. Gage, our "Aunt Fanny" of
 old,
 Whose voice rang for freedom when freedom
 was sold.
 And Husband, and Etheridge, and Harlan and
 Case,
 Livermore, Alcott, Hancock and Chase,
 And Turner, and Hawley, and Potter and Hall,
 Ah! the list grows apace, as they come at the
 call:
 Did these women quail at the sight of a gun?
 Will some soldier tell us of one he saw run?
 Will he glance at the boats on the great west-
 ern flood,
 At Pittsburg and Shiloh, did they faint at the
 blood?
 And the brave wife of Grant stood there with
 them then,
 And her calm, stately presence gave strength
 to his men.
 And Marie of Logan; she went with them too;
 A bride, scarcely more than a sweetheart, 't is
 true.
 Her young cheek grows pale when the bold
 troopers ride.
 Where the "Black Eagle" soars, she is close at
 his side,
 She staunches his blood, cools the fever-burnt
 breath,
 And the wave of her hand stays the Angel of
 Death;

She nurses him back, and restores once again
 To both army and state the brave leader of
 men.
 She has smoothed his black plumes and laid
 them to sleep,
 Whilst the angels above them their high vigils
 keep:
 And she sits here alone, with the snow on her brow—
 Your cheers for her comrades! Three cheers for
 her now.
 And these were the women who went to the
 war:
 The women of question; what did they go for?
 Because in their hearts God had planted the
 seed
 Of pity for woe, and help for its need;
 They saw, in high purpose, a duty to do,
 And the armor of right broke the barriers
 through.
 Uninvited, unaided, unsanctioned oft times,
 With pass, or without it, they pressed on the
 lines;
 They pressed, they implored, till they ran the
 lines through,
 And this was the "running" the men saw them
 do.
 'T was a hampered work, its worth largely lost;
 'T was hindrance, and pain, and effort, and
 cost:
 But through these came knowledge,—knowledge
 is power.—
 And never again in the deadliest hour
 Of war or of peace shall we be so beset
 To accomplish the purpose our spirits have
 met.
 And what would they do if war came again?
 The scarlet cross floats where all was blank
 then.
 They would bind on their "brassards" and
 march to the fray,
 And the man liveth not who could say to them
 nay;
 They would stand with you now, as they stood
 with you then,
 The nurses, consolers, and saviours of men.

Clipper Ship

The clipper ships of the 1840s portrayed a romantic image of plying the seven seas as the sleek ships' white canvas sails billowed in the wind as they cut across the ocean waves. These ships were beautiful to look at and designed for speed, but built for a very practical purpose.

The American colonies had won independence from Great Britain in 1783. The new country needed money, so trade was essential both within the United States and with other countries. American ships had to compete with those from countries that had long-established trade routes, and one way to do that was to be faster.

American schooners raided British vessels during the War of 1812. Schooners were small, agile, and maneuverable. They had two masts with lots of canvas sails to capture the wind. Larger, less maneuverable British ships could not catch them.

The United States defeated the British, and the war ended in 1815. Ships built during peacetime were designed to carry cargo. Flat-bottomed ships held more, but they were slower, sluggish in the water, and easily caught by the ships of other countries or boarded by pirates. Peace had been established on paper between the United States and Great Britain, and though neutral in conflicts between Great Britain and France, American ships were still boarded and had their cargo stolen. Again, the United States needed fast ships to compete.

U.S. trade with the West Indies and South America was for fruit and other food, coffee, and spices. Slow ships were raided and lost their cargo, or fresh cargo spoiled on too long a voyage home. Ships needed to get to their destinations quickly and return home quickly. American ships changed their design to increase speed while still allowing room for cargo. The front section, or bow, of the ship was sharpened, and the ship's bottom, or keel, was built less flat.

Another way for American ships to compete was to offer new services. Prior to 1818, ships had left port when they had enough cargo or passengers to make a profit and when the weather permitted. Starting in

January 1818, the Black Ball Line offered a departure schedule. These so-called "packet ships" sailed the first and 16th of the month in any weather, with full cargo and passengers or not. They carried mail packets and passengers from America to Britain and brought immigrants, cargo, and mail back. The trip from New York to Liverpool took about 23 days. The fastest time was 15 days.

The design of ships continued to develop as builders sought to make each ship faster than the last. The hull of the schooner curved more and evolved into a design for ships known as "Baltimore clippers." The term "clip" means to go fast. Instead of riding on top of the waves, clippers were described as cutting through the ocean like scissors.

Baltimore clippers were used for trade along the eastern United States and the Caribbean. They were built to be fast to carry spoilable cargo back to U.S. ports. They also sailed to Africa and brought slaves to plantations in Cuba and the United States.

One of the first Baltimore clippers was the schooner *Ann McKim*. The ship was built in Baltimore in 1832, weighed 494 tons, and was 143 feet long. It was the fastest merchant ship at the time. Its first voyages were to China. Later voyages to South America recorded its fastest sailing times of 51 days from Valparaiso, Chile, to San Francisco (1849) and 47 days from San Francisco to Valparaiso (1850).

The British East India Trading Company was established by British Parliament in 1600 to handle trade with Great Britain and her colonies. It controlled most of the ports in British-controlled parts of China and East India by the late 1700s. As a Parliament-sanctioned legal monopoly of these ports, its profits were huge. Many complained about the lack of free trade. The Company's power and influence only decreased when non-East India Trading Company ships were allowed to sail and trade in the Orient beginning in 1832.

Considered by some to be the first true clipper, the American ship *Rainbow* was built in 1845 for travel from New York to Canton. It weighed 750 tons and had three masts. Its first voyage to Hong Kong took 102 days. Its return voyage took 108 days.

Gold was discovered at Sutter's Mill, California, in 1848. The California Gold Rush was in full swing by 1849, and so was the demand for the fastest route to the West Coast. Miners wanted to get to San Francisco and nearby Sutter's Mill, and merchants wanted to get there to sell supplies and mining equipment.

The East India Trading Company's power eroded even more in 1849 when navigation laws were repealed. This opened Great Britain's and its colonies' ports to all ships.

Clippers were known for sailing day and night in good weather or bad. They were fast because they had sharp-lined hulls in proportion to their beam and carried lots of canvas. To reach these additional trade routes in India, China, and California they were redesigned again.

The *Stag Hound* was built in 1850 by prominent shipbuilder Donald McKay. The ship weighed 1,534 tons and carried 11,000 yards of canvas sail. The *Stag Hound* was called an extreme clipper because it was the longest and largest merchant ship at the time. On its best day, it sailed 358 miles.

The 1,800-ton *Flying Cloud* was built the following year. On its maiden voyage from New York to San Francisco via Cape Horn (the southernmost tip of South America), the ship completed the voyage in 89 days and 21 hours. The ship broke its own record in 1854, and that record of 89 days and 8 hours held until 1989.

The *Great Republic*, at over 4,500 tons, was the largest clipper ship ever built. It measured 335 by 53 by 38 feet. Completed in 1853, it was destroyed in dock by a wharf fire before its maiden voyage. The ship was rebuilt and had over 15,000 yards of canvas sail. A 15-horsepower engine raised its sails and moved cargo.

There were two water routes to get from the East Coast of the United States to the West Coast. One was by sailing south around Cape Horn and then north to San Francisco—over 13,000 nautical miles. The shorter route of 5,000 miles was by sailing south to Panama, crossing by land the fever- and disease-ridden Isthmus of Panama, and then going by ship again north to San Francisco.

Clipper ships ruled the oceans for about a decade. While the *Great Republic* was powered by wind in its sails but used an engine to move cargo, competition from ships powered not by wind but by steam engines started to grow. A few sailing ships had steam engines as backup power if there was no wind. Some ships used steam engines to maneuver in harbors. Steam-powered ships crossing the open ocean were just a matter of time.

Demand for clipper ships declined after the opening of the Suez Canal in 1869. The canal allowed ships from European ports to reach the Pacific Ocean and western United States much faster and safer than by the Cape Horn or Isthmus of Panama routes. Ships' design changed to have fewer sails, fewer sailors, more cargo, and more profit.

The *Ann McKim* was dismantled in Valparaíso, Chile, in 1852. The *Rainbow* left New York for China via Valparaíso and was never seen again. The *Stag Hound* burned off the coast of Brazil in 1863. The *Flying Cloud* was destroyed by fire in 1874 in Saint John, New Brunswick. The *Great Republic* foundered in a hurricane off Bermuda in 1872. These were just some of the clipper ships of the time.

Although the clipper ship era was short, it exemplified a time of innovation and experimentation. Competition for trade routes created competition between captains and crew to be the best: a fast ship could be built to be even faster.

Primary Document: Excerpts from the Journal of Alexander Van Valen Describing His Journey to California via Clipper Ship (1849)

In 1849, Alexander Van Valen traveled from New York to California by clipper ship. Van Valen discovered that conditions aboard ship were significantly less pleasant than shipping advertisements had suggested, but he remained impressed with the speed of travel.

Wednesday Feb 14, 1849. 6 a.m. Cloudy. Weather mild, light winds and variable, we now begin to feel the inconvenience of a Small Ship crowded with Passengers, a Small Cabin crowded with Baggage & no Ventillation, and to make the place still more disagreeable especially in the warm Latitudes the Cabin is furnished with 3 or 4 dirty & half trimmed

Oil Lamps, which emits a Smoke equal to a Blast furnace. 12 m Lat 10° 25' North Long 25° 05' West. nothing worthy of note occurred the remainder of the day. I find it quite a task, especially one like myself who have allways been engaged in other pursuits than writing, to find material about which to write. there is much of a Sameness on Ship Board day after day, and seldom anything occurs to change the Monotony of the Scenes. Thursday Feby, 15, 1849 5 am. Arose this morning and took a Bath, which is performed in the following maner, some 4 or 5 club together, one of which takes a Bucket, draws the water and dashes it upon the rest & Visa Versa. Weather warm light wind from the North East. The Temperature of the weather about the same as July or

August in New York. 12 m, Lat 8° 01' North. Long 25° 05' West.

Wednesday May 23rd 1849. Weather Cool. Wind South blowing a good Stiff breese. we dropped Anchor in harbour opposite the City of Valparaiso about 12 M. making the Passage from St. Catherines to this place in 53 days and from New York including 14 days stoppage at St. Catherines in 121 days. Valparaiso lies in Lat 32° 51' South. Long 73° 57' West. We had a beautiful Sail along up the Coast this morning going at the rate of 10 to 12 Miles an hour under a full spread of Canvass. 6 other vessels going in at the same time, giving us a fair trial of our Barks Sailing qualities. And I must say she did her part nobly. if the chase had been of a few hours longer duration I think we would have beat the whole fleet. We had a fair opportunity of viewing the beautiful Mountain Scenery along the Coast, which for grandeur, magnificence and wildness, exceeded anything of the Kind it has been my lot to behold before. and farther back from the Coast range the lofty Andes, raising their bold Peaks and piercing the clouds with their Snow-capt Summits. Constrasting beautifully with the dark foliage of the Mountains below, the Harbour presented quite an imposing appearance. there were lying at anchor upwards of 50 vessels, of all classes.

Clothespin

The clothespin is a fastener used to affix clothes to a clothesline. The clothespin is different from the clothes-peg, a two-pronged, single piece of wood, in that the clothespin is made up of two separate pegs with a central spring. “Mother” Ann Lee, leader of the Shakers, an American religious group, invented the clothes-peg in the 1700s. Clothes-pegs remain in use today, both for laundry and for decorative and crafting purposes. Romani people, commonly known as gypsies, also made clothes-pegs, generally from split pieces of willow.

David M. Smith patented the modern clothespin in 1853. Spring-loaded clothespins are considered sturdier than clothes-pegs and capable of holding heavier laundry loads. In the three decades that followed Smith’s 1853 patent, 146 different designs for clothespins were submitted to the U.S. Patent Office.

In the 21st century, clothespins are considerably less common than they used to be, in part because of the proliferation of electric or gas home dryers. A renaissance in line drying, brought on by environmental and energy conservation concerns, has led to a resurgence of the clothespin.

Peg A. Lamphier

This woodcut shows a traditional clothes peg and one version of many newly patented clothes pins, ca. 1860. Shakers invented the one-piece wooden clothes peg in the 1700s. Previously, laundry hung on bushes, tree limbs, or lines to dry. (Bettmann/Getty Images)

Coal-Mining Technologies

Soft coal, or bituminous coal, is a combustible, sedimentary rock primarily used as a cheap and dirty energy resource outside of cities or in trains. Hard coal, or anthracite, is clean and smokeless and used in cities, often to replace wood. In America, commercial coal mining began during the 1740s in Virginia. Coal mining is categorized in two major ways; it can be mined from the surface or underground.

Types of surface mining involve strip, auger, open-pit, and mountaintop removal. There are two subcategories for stripmining: area and contour. The types of underground mining are: room and pillar, longwall, shortwall, continuous, and blast. Each of these mining processes involves different tools. Underground, the tools often used are: the longwall machine, continuous miners, roof bolters, shuttle cars, underground rail, ventilation fans, rock dusters, and scoops. Aboveground,

the equipment used includes: draglines, shovels, loaders, haul trucks, and other vehicles.

Stripmining can be done in areas or contours. Stripmining in an area is the most common type of mining. Area stripmining takes place on flat terrain, while contour mining takes place on steep terrain. Stripmining involves removing layers of minerals. Auger mining is a supplemental mining technique and is done on hillsides. Auger mining is boring near horizontal holes to recover specific areas of coal. Open-pit mining is used when multiple seams of coal lie in one location, and these tend to be vertical seams. The operation tends to stay in one area, deepening and widening the hole. Mountaintop removal is mostly used in areas that require major topographical change. It involves removing an extreme amount of overburden, or extra material, to reach coal seams. The overburden is usually placed into a nearby valley to even out the levels of the two areas.

Underground mines are named based on modes of access; hence drift mines are entered horizontally into the side of a hill. Slope mines begin in a valley bottom with a tunnel sloping down to the coal to be mined, and shaft mines involve a vertical shaft with an elevator taking miners from the surface down to the coal. Room and pillar is the oldest form of underground mining. In room and pillar, mining is done in a vertical underground area, leaving supports unmined.

Longwall is similar to room and pillar except there are no supports left behind. A longwall machine digs a long hole, supporting only the roof above itself. The roof behind it may cave in and is removed on a conveyor following the machine. For continuous mining, a machine mines until it reaches the end of a hill, and the material is excavated afterward. Blast mining is mining with the use of explosives. This is very risky and is usually only done if a tunnel must be built and bedrock sits in the way.

Early coal mining took place very near to the surface. It used either open-pit or room-and-pillar mining techniques, using workers to dig. The use of open pit and room and pillar, while only 40 percent effective then, was enough to spark the Industrial Revolution, where the invention of the steam engine called for even more coal. Underground mines required, and were constantly tested for, firedamp. To clear out firedamp, the mines were ventilated by fires or stream fans at the bottoms of vertical shafts. The use of wood to support the roof and prevent it from caving in came about around 1800. Coal mining remained unaffected by most inventions during the Industrial Revolution, as it was not cost-effective to power any relevant machinery. However, steam-powered draining machines helped remove water from flooded mine shafts. Children worked like longwall machines, fitting into small tunnels and mining only enough for their size. Either that, or they did tasks for the miners like carrying lights and shutting trapdoors. In 1889, the top-producing coal states were Pennsylvania, Illinois, Ohio, West Virginia, Iowa, and Alabama.

There were many miner strikes after a United Mine Workers union formed in 1890. This helped bring high wages and many benefits for miners. Miners risked cave-ins, floods, gas explosions, chemical poisoning, and electrocution.

Pockets of gas are known as “damp.” There are many different types of damp. Black damp consists of nitrogen and carbon dioxide and can suffocate miners. Firedamp is flammable gas that sometimes causes coal dust to ignite. Afterdamp is the gas left after an explosion of firedamp. Stinkdamp is usually hydrogen sulfide gas, which is toxic and explosive. Whitedamp combines all of the damps and is a toxic, explosive gas with no smell. Because of all the firedamp explosions

and other mining incidents, there was the invention of the safety lamp, which detected but would not ignite firedamp. Most safety lamps worked by restricting air-flow to a candle. The first lamps required constant power to pump air through water to filter out any damp. They were heavy in water weight and required to be held level to even work. There was also a lamp that provided light with sparks, which, after an explosion, prove capable of lighting firedamp. The Davy, Geordie, and Clanny lamps were standard safety lamps that had wire gauze filters around them. They would burn brighter when near firedamp. They failed to provide significant light, and they could still ignite firedamp, so they were mostly used as a detection system. Other firedamp-proof lights included jars of fireflies or bioluminescent fish scales. Finally, the electric lamp debuted in 1910.

There was great need for coal to power many inventions during the Industrial Revolution. Soft coal was a cheap source for powering steam engines and hot enough to make coke for steel. Coke is a fuel with few impurities and high in carbon; it is made from bituminous coal and is low ash and low sulfur. It produces high heat and no smoke. Melting iron and coke produces steel.

When exposing coal seams, we run the risk of causing underground fires that can leave the surface uninhabitable. Mining coal seams can affect groundwater, raising acidity. Burning coal also puts chemicals into the air that can lead to acid rain, and most notably, a carbon dioxide increase in the atmosphere. Coal is a nonrenewable resource.

As of 2016, most coal is stripmined with the use of heavy machinery. A notable piece of machinery is the Bagger 293, a bucket-wheel excavator, which holds the record for being the largest terrestrial vehicle. People are not exposed to dangerous, unventilated mineshafts when machines mine for coal aboveground.

Coal has become less effective as a power source, but it generates 30 percent of U.S. electricity. Mines are approaching the end of their useful life as natural gas and other alternatives take hold. In 2016, 25 percent of coal producers filed for bankruptcy. In 2009, the United States produced 973 million tons of coal, still the second-highest country in production. While

coal may be phased out of our energy supply at some point, coal was a stepping-stone we used to reach toward even better materials to provide us energy.

Coil Magnet/Electromagnet

The coil magnet, or electromagnet, is essentially a bar of iron wrapped with wire. When electric current is applied to the wire, it produces a magnetic field. Electromagnets can be used to lift or move objects, and because their magnetism can be controlled as the current is turned on and off, they can function as switches.

The first practical electromagnet was built in 1825 by English scientist William Sturgeon (1783–1850). His apparatus consisted of a seven-ounce curved bar of magnetized iron wrapped loosely with 18 turns of bare copper wire. Sturgeon coated the magnet with varnish to prevent it from shorting out with the uninsulated wires. The electromagnet was able to lift a 9-pound piece of iron, but the magnetic fields quickly collapsed, making Sturgeon's apparatus little more than a tool for demonstrating principles of electricity and magnetism.

American engineer Joseph Henry (1797–1878), a pioneer in the fields of electricity and magnetism, was intrigued by the possibilities of Sturgeon's electromagnet. He tinkered with the design, using cotton-wrapped insulated wire instead of bare copper, and he tightly wrapped several hundred turns of wire around the iron core. The result was a very strong electromagnet, much more powerful than Sturgeon's.

Meanwhile, other scientists, notably Dutch researcher Gerard Moll, were also working on making large electromagnets. Some of Moll's work was published in the fall 1830 issue of the *American Journal of Science and Arts*, but Henry had been slow to document his work and only managed to have an extract of a letter to the journal's editor, Benjamin Silliman (1779–1864), published in the appendix.

During the 1830s, Henry built a number of large electromagnets, including a 21-pounder that could lift 750 pounds. His most famous electromagnet was the one he built in 1830 for Silliman, then a professor of science at Yale. The monster magnet, which came to be known as the "Yale magnet," weighed an impressive 82-and-a-half pounds and could lift more than a ton.

Moll's electromagnets were supersized versions of Sturgeon's original, and both required large batteries. What differentiated Henry's improved electromagnet from the other designs was that he could power his electromagnets with small batteries. Henry constantly experimented with getting the most performance from small power sources. He discovered that by connecting many small batteries in a series, rather than using one large battery, he could get enough power to send a signal down a 1,060-foot length of wire and ring a bell.

The small power source was what made Henry's electromagnets so useful. They were used in the creation of the first electric doorbells (credited to Henry), as well as in telephone speakers and as relays in long-distance telegraphy.

Colgate, William (1783–1857)

Inventor and businessman William Colgate's efforts and innovations in the field of personal hygiene had a lasting impact on American society. A deeply religious man, he dedicated much of his life and wealth to the church.

William Colgate was born on January 25, 1783, in Kent County, England, to Robert Colgate, a farmer, and Sarah Colgate. Robert Colgate was an outspoken supporter of the American pursuit of independence, and his public support for the rebellion led to continuing harassment by British authorities. In March 1798, after being warned by family friend Prime Minister William Pitt that they were in imminent danger of being imprisoned, the Colgate family left England for the United States, eventually settling in Maryland. Robert Colgate formed a partnership with a local man and set up a soap-and-candle business in which his son, William, helped.

When the partnership dissolved, Robert sought to return farming while William pursued business on his own. However, lacking sufficient capital, William's first venture failed. Undeterred, in 1804, William Colgate headed to New York City to make another attempt. He soon found work with a soap maker, working with Slidell and Company. He expanded his knowledge of the soap business, and when their business shut down after just two years, he struck out on his own, establishing an operation that made and sold starch, soap, and candles. He achieved immediate success, utilizing a number of innovations, including the introduction of perfumed soap to the American consumer. Colgate also made individual bars of soap available to customers and introduced the first standardized bars of the same size and weight. At one point, the company's product line featured Pale Soap, White Windsor, and Honey brand soaps as well as Pearl Starch and a variety of shaving soap products.

Colgate pioneered the use of newspaper advertising; the first Colgate ad appeared in a New York newspaper in 1817. He also was willing to expand more broadly than was the norm, first opening a starch factory in Jersey City, New Jersey, in 1820. In 1847,

going against all conventional wisdom, he moved his company from the Dutch Street headquarters it had outgrown in the middle of New York City to a Jersey City location.

While the company thrived and expanded, Colgate also led a full life as a citizen in the greater New York area. He married Mary Gilbert in 1811, and the couple had three sons. He often told a story about meeting a canal boat captain just as Colgate was preparing to go off on his own. The captain told him that someone was going to be the leading soap maker in New York and that it could be Colgate if he made an honest, quality product while also giving God his due. Colgate said he took those words to heart, seeking to produce nothing but quality products while also promising to tithe a generous portion of his wealth to the church. He had been baptized at the First Baptist Church of New York and was an active Baptist, known as Deacon Colgate to other church members. In addition, he served on the board of managers of the American Bible Society and as its treasurer. Later splitting with that organization, he helped found the American Bible Union in 1850, where he also served as treasurer. Colgate and his family were active and generous supporters of Madison University in Hamilton, New York, and in 1890, long after his death, it was renamed Colgate University in recognition of his and the family's longtime support.

William Colgate died on March 25, 1857, in New York. He is buried in Brooklyn, New York.

Colored Female Free Produce Society

The Colored Female Free Produce Society (CFFPS) grew out of the desire of many Americans, Northern and Southern, to decrease their own complicity with slavery. One method was to boycott goods such as sugar, cotton, and rum that were either harvested or manufactured by enslaved persons. Products that were not made by slaves were considered to be “free,” prompting some antislavery activists to organize around the idea of “free produce.” Abolitionists sought to decrease the market demand for products made by involuntary laborers by refusing to buy slave-made goods. The CFFPS was a product of this moral, humanitarian reform impulse of a group of dedicated African American female abolitionists in the Philadelphia area.

In a widely read 1811 essay, Long Island Quaker Elias Hicks (1748–1830) wrote that no one could “plead the necessity . . . to indulge themselves in the luxuries raised by the labor of slaves.” Hicks was echoing the sentiments of Quaker John Woolman (1720–1772) who had championed the “free produce” ideology as early as the 1770s. Dozens of free produce organizations had been formed by the start of the 1830s.

Black abolitionists in Philadelphia formed a distinct group in 1830 called the Colored Free Produce Society of Pennsylvania. Black women in the movement, a majority of them members of Bethel African Methodist Episcopal Church, broke off to create the Colored Female Free Produce Society in 1831. This group preceded the widely recognized Philadelphia Female Anti-Slavery Society, founded by Lucretia Coffin Mott (1793–1880) and other prominent female Quaker abolitionists, by two years. Among many similar reform groups, black and white women were compelled to create their own organizations when they encountered sexism in male-led organizations. Many historians trace the beginning of the women’s rights movement to these groups, which created for women a platform for public speaking and activism, as well as awareness of gender-based oppression.

The Colored Female Free Produce Society worked toward its goals through public promotion of its ideals, beseeching women, as household managers, to take

the moral high road in their purchasing habits. One of the earliest free produce advocates in the United States was a Pennsylvania woman named Alice Jackson Lewis, who spoke publicly about free produce at the turn of the century, encouraging her fellow Quakers to refrain from using sugar produced in the West Indies by slave labor. At this time, women were not supposed to engage in public speaking or to speak to gender- or racially integrated groups. Thus, the rhetorical cause of free produce offered a unique opportunity for women to speak on what was to many men an acceptable topic. For many black abolitionists, an obligation to abstain from slave-made goods seemed both a personal and political imperative. Many Americans joined the free produce movement, including well-known speaker and writer Frances Ellen Watkins Harper (1825–1911) and the prominent free black Forten family of Philadelphia.

The CFFPS also actively promoted merchants who dealt in free labor goods, advertising on their behalf in addition to patronizing their stores. Members were expected not only to abstain from purchasing slave-made goods in their own lives but to set an example to the larger abolitionist community and in their regions. Free produce fairs were held in New York and Midwestern states, where attendees could buy literature about the movement and merchandise branded with abolitionist rhetoric, including the slogan “Am I not a woman and a sister?” Gender-based slogans not only invoked a unity of femininity in hopes of adding more members to the cause but also played on the abolitionist notion that slavery damaged both free and slave women. Lydia White ran a successful free produce store in Philadelphia for 16 years. Nevertheless, few of these stores lasted beyond 1840, and critics rejected the free produce cause as idealistic. While little documentation has survived about the members of the CFFPS, what remains points to a legacy of staunch abolitionists among black and white American women. Grassroots organizations such as the free produce societies of the 1820s and 1830s served as a springboard for many women into a career of activism.

Colt, Samuel (1814–1862)

American gun inventor and manufacturer Samuel Colt significantly changed the American market for hand-guns, improving both accuracy and safety in a manner that made Colt a watchword for quality.

Colt was born in Hartford, Connecticut. His father, Christopher Colt, was a textile manufacturer, and his mother was Sarah Caldwell Colt. Sam Colt gained an interest in finding out how things worked, taking them apart to discover how they functioned. He seems to have developed this interest through two sources: going to his father's textile mill in Ware, Massachusetts, and working at a neighbor's farm. Interestingly, among the things he took apart were his father's guns and rifles.

He attended Amherst Academy briefly to study navigation when he was 16; he was asked to leave because of his behavior. His father sent him to sea on the *Corvo* to learn navigation firsthand. The trip lasted nearly a year. It was at sea that he first came up with the model of a six-barrel cylinder with a locking pin and barrels. Aboard the *Corvo*, Colt developed a keen interest in the ship's wheel. It was his genius to apply the wheel's ability to spin or be locked in a fixed position, using a clutch, to firearms. He thus created a single-shot gun that could fire six bullets in rapid succession. He carved the model out of wood. Later, he swapped out the rotating barrels for a rotating cylinder that held the bullets.

Colt received a British patent in 1835 and an American patent in 1836. Soon after, he founded his own company in Paterson, New Jersey—the Patent

Arms Manufacturing Company. However, Colt was shrewd enough to keep the patents to himself, filing for them as an individual. The weapons he had improved were used in settling the frontier and in the battles during the process. However, initially, sales were slow. The Mexican War of 1846 to 1848 spurred sales as the United States government placed an order for 1,000 Colt revolvers. This success led eventually to the opening in 1855 of Colt's enormous manufacturing plant, then the world's largest private weapons factory. The factory was not just large; it also used the most advanced manufacturing methods. The Colt revolver became the most famous gun in the world and was used during the American Civil War (1861–1865). Colt was a strong and clever promoter. Perhaps he had gained that skill during his two years as the host of a road show that promoted nitrous oxide. "Dr. Coult," as he termed himself, made enough money to fund his perfection of the Colt revolver and to hire gunsmiths to make prototypes.

Before this success, there had been a business failure on Colt's part. First, the army had rejected the use of Colt's weapons because it deemed a percussion cap to be too new and possibly unreliable. Even though Colt had sales in Texas and Florida during the Second Seminole War (1835–1842), they did not raise the money that Colt needed to put on a prosperous front for potential clients. Colt was reduced to a sales agent when the shareholders took over his company. When the company began to fail, he joined forces with Samuel F. B. Morse to install a waterproof cable in the Atlantic Ocean. Unfortunately, the line was abandoned after being built from the New York Merchant's Exchange to Sandy Hook, New Jersey, but the inventors had proven that a cable could send electricity underwater.

Colt recovered from these setbacks and founded his new company in Hartford, Connecticut. Elisha K. Root (1808–1865) became his manager. Root was mechanically minded and hired competent, innovation-minded engineers and mechanics. The Colt Patent Fire-Arms Manufacturing Company also opened a branch in England. This was when Colt became a standard for quality. As a great promoter, Colt made his brand part of the great American myth, even having the artist George Catlin put the Colt gun into what became iconic American paintings.

The Civil War led to a great increase in sales. Colt sold over 100,000 weapons to the Union side. However, the strain of the increase in sales and the longer hours helped end his life at 47. His wife inherited his company, and Root continued as manager until 1901, when the company was sold. It continues its operation in Hartford, Connecticut, today. Interestingly, Sam Colt never fired a gun at any human being, although his brother murdered a man with a Colt weapon.

Colt Revolver

Samuel Colt (1814–1862) got the idea for a multiple-shot revolver when he was a teenager. Six years later, Colt patented the revolving gun and founded the company that would mass-produce it.

Colt was born in Hartford, Connecticut. When he was 10 years old, he worked in his father's dyeing and bleaching business and learned about chemistry. He didn't like school, but he liked to read about guns. He took apart several single-shot pistols to see how they were constructed and how they worked.

Modern guns fire a cartridge that contains a bullet, gunpowder, and an explosive cap. Guns used in the early 19th century required that each component be loaded manually. Gunpowder was poured down the

barrel of a flintlock-style gun, followed by a steel ball. A clamp called a "lock" held a piece of flint. When the gun's trigger was pulled, the flint struck a metal plate and sparked. The spark ignited the gunpowder, sending the steel ball down the barrel. The load-reload process was slow, and only one shot could be fired per load.

Many had tried to produce a multiple-shot fire-arm. Variations included multiple-barrel guns or multiple chambers, but none were dependable. The goal remained a multiple-shot firearm that was accurate and reliable.

Colt was a deckhand on a cargo ship when he was 16. During the yearlong, round-trip voyage from Boston to Calcutta, Colt watched how the ship's wheel worked. The wheel turned on a ratchet-and-pawl system. When the wheel turned, a gear with teeth rotated. A pawl, or lever, slid over the gear's teeth as long as the gear moved in one direction. If the direction of the wheel reversed, the pawl locked the gear in place, preventing movement.

While on the voyage, Colt carved a wooden gun with multiple chambers in a cylinder that revolved. When Colt got back to Boston, with some financial help from his father, he hired a gunsmith to build a metal prototype. The prototype exploded upon firing. Powder leaked between the chambers, so instead of firing one at a time, several exploded at once.

Colt worked to improve the design of the revolver. He lectured throughout the eastern United States and Canada about the newly discovered gas, nitrous oxide, to raise money to produce another prototype. Colt explained the properties of laughing gas and gave demonstrations using audience member participation. His lectures were very popular.

Colt made improvements to his earlier design. The partitions between the chambers were strengthened to eliminate crossover firing. When Colt had enough money, he gave this design to a different gunsmith in 1835. This prototype worked.

The Colt revolver had a revolving cylinder with six openings or chambers. Each chamber was loaded with gunpowder followed by a lead bullet. The bullet was pushed into a chamber by a rod under the barrel. Pulling the gun's hammer rotated the cylinder. As a chamber lined up with the barrel, it locked in place. The hammer released when the trigger was pulled.

The hammer struck a percussion cap, which ignited the gunpowder and pushed the bullet down the barrel.

Colt's improved design received patents in England and France in 1835 and one in the United States (patent number X9430) in 1836 for the revolving gun. Once Colt had a patent, he found it easier to obtain investors' money to build a factory. The Patent Arms Manufacturing Company in Paterson, New Jersey, opened that year.

Customers included the newly formed Texas Rangers law enforcement agency, but orders were slow. Many were skeptical of the new technology, including the U.S. government, which chose to continue using single-shot pistols. The economic panic of 1837 did not help with sales. The company declared bankruptcy in 1842 and closed.

But Colt continued to promote the revolver. He gave demonstrations on how the gun worked. He presented gifts of engraved revolvers to legislators and other decision makers.

Five years after the Paterson plant closed, the U.S. government needed weapons to fight the Mexican-American War (1846–1848). The government placed an order with Colt for 1,000 revolvers. Colt contracted with Eli Whitney Jr. to fill the order in Whitney's Connecticut factory. This increase in sales gave Colt enough money to rent a factory in 1847 for manufacturing guns. He built a new factory in Hartford, Connecticut, in 1852. It was state of the art, with gas lamps and a ventilated work area. Workers were paid \$5 a day and given houses to live in.

The innovative machinist at the factory, Elisha K. Root (1801–1865), built many of the machines that produced gun parts. Parts were measured and were very similar in size and shape, but a worker finished or buffed parts as needed to assemble a gun.

Colt attended the first World's Fair in London in 1851 and the first World's Fair held in the United States in New York City in 1853 to promote the revolver. Colt made improvements to the revolver's design and received additional patents in 1850 and 1859. Colt died in 1862 at age 47, and Root became president of the company.

The revolver's design changed over the years. The single-action gun that required that the hammer be

cocked by hand and the trigger pulled to fire became the double-action revolver in which pulling the trigger moved the hammer back, rotated the cylinder, and released the hammer to fire the gun. Cartridges have been used for over 100 years. The revolver's dependability and accuracy remain the reasons that it is still in production.

Columbiad Cannon

Invented in 1811 by Colonel George Bomford, the Columbiad cannon was crucial in providing the United States with coastal defense in the War of 1812, as well as being an important artillery piece during the Civil War. The Columbiad was a cast-iron, smoothbore cannon that came in 7, 8, and 10-inch diameters.

Following his graduation from West Point Academy in 1805, George Bomford was assigned to an assistant engineer position at New York Harbor. In 1808, he was moved to the Chesapeake Harbor, where he served until 1810, after which he was promoted to superintendent engineer for the construction of Castle Williams at New York Harbor.

In 1811, he developed the first heavy artillery that could be utilized in defense against naval forces: the Columbiad cannon. It could fire 50-pound projectiles at up to 4,000 yards, making it effective against enemy ships. The army equipped a handful of bases around

the country with this new weaponry. Many more would have been produced if not for the high cost of manufacturing. The cannons typically weighed 15,000 pounds apiece, so maneuverability was not an option. Armies would normally place them in prime locations to ensure maximum battlefield coverage.

The Columbiad's successor, the Rodman gun, improved on several key aspects of the Columbiad. These included weight, firing distance, and the durability of the iron castings. The design was revolutionary because it utilized a hollow-cast concept. Thomas Jackson Rodman designed the hollow casting to make the cannon considerably less vulnerable to splitting and cracking—or, worse, explosion. Previous cannons, like the Columbiad, cooled from the outside inward after being fired. As their castings cooled down unevenly, they would shrink and crack. Rodman's method allowed the cannon to cool from the inside out, which made for a much more effective and durable gun. Nonetheless, the Rodman gun is essentially just an improved Columbiad. The same could be said of the Dahlgren gun, designed by John Dahlgren as a safer naval cannon.

During the Civil War, the Confederate Army used Columbiads almost exclusively, in part because they had no facilities for making their own cannon. It only had what it had confiscated from the United States when the Confederacy seceded. Columbiads were effective against Union ships that were made of iron. At the end of the Civil War, many Columbiad cannons remained at coastal military battlements. This was probably due to their weight, which made them difficult to move. They were also less effective against new weapon advancements.

Many of these cannons can still be seen adorning city halls, parks, and other government establishments throughout the country. It could be said that the Columbiad cannon serves as a symbol of patriotism. The imagery of cannons firing goes hand in hand with the shaping of the United States and freedom. Colonel Bomford could very well have conceptualized one of the most important American inventions of all time.

Combine Harvester

The combine harvester was invented by Hiram Moore in 1835. It is a machine used to harvest grain crops by combining reaping, threshing, and winnowing in a single process.

Patrick Bell, a Scotsman, designed the first combine reaper in 1826, but he did not patent it. Nor did he put his machine into mass production, so few were available in the United States. Bell's combine was pushed by horses, while other early versions of harvesters were either pulled by ox, mule, or horse. Moore's first combine required 20 horses to pull it and cut a 15-foot swath. Later versions of Moore's combine proved wider and lighter, though combines that required 20-horse teams were common on farms, particularly in the Midwest, until the early 20th century.

In 1886, George Stockton Berry developed a steam-powered combine that ran on burning straw. These combines were the first to be self-propelled, but Berry only built seven of them, so they were exceedingly rare. In 1911, Holt Manufacturing Company produced the first gasoline-powered combine.

Today's combines are self-propelled and use diesel engines for power. A significant advance in the design of combines was the rotary design. This innovation in the agricultural machine allowed for more crops to be harvested at a higher and more efficient rate. Among the crops harvested with a combine are wheat, oats, rye, barley, corn, soybeans, flax, sunflowers, and canola. The waste left behind on the field is made up of the remaining dried stems and leaves of the crop, which is either chopped and spread on the field or left for feed and bedding for livestock.

In the early 1900s, International Harvester started making combines that were pulled by horses, and five years afterward, Case Corporation and John Deere developed combines that were pulled by tractor,

A horse-drawn combine works a California grain field in 1902. The combine harvester was invented by Hiram Moore in 1834 to ease the work of farming and expand food production for the new nation. (Library of Congress)

requiring a second engine aboard the harvester to power its functions. The Great Depression significantly affected the manufacturing of farm equipment; it halted productivity, and farmers had to return to their old methods of harvesting. Harvest time is the final critical period in making a crop, and every owner wants crops to grow safely. The Great Plains in particular have a tricky climate, and a few days of delay may bring on a windstorm or hailstorm that can greatly affect crop production. Harvesting was a dangerous task at times and required numerous hours on the field far into the night, just so a farmer could make sure that everything was running properly and efficiently. After World War II, many farms started to use tractor-drawn combines, also called “pull-type” combines. The tractors provided a source of power, whether mounted on the tractor itself or pulled along on other machinery.

One example of the farm tractor was the All-Crop harvester series made by Allis-Chalmers. These particular harvesters were able to harvest flowers as well as different grasses. These machines are still in current use and are well known for their dependability and low maintenance, but their small size isn’t well suited to the large farms of today.

A new system of leveling known as the “hydraulic hillside leveling system” was introduced in the Palouse region of the Pacific Northwest in the United States. This system allowed for combines to harvest steep slopes with as much as a 50 percent incline. The first leveling technology was developed by Holt Company, a California firm, in 1891. Modern leveling was then being addressed by the inventor and engineer Raymond Alvah Hanson, who patented the mercury switch system in 1946. Hillside leveling increases threshing

efficiency, and the system can change its center of gravity, allowing the combine to maneuver without tipping on dangerously steep hills. Another technological feature of combines is a continuously variable transmission, which can vary ground speed while maintaining a constant threshing and engine speed. This single-speed transmission also allows for seamless changes through a series of varied gear ratios. Later on, hydrostatic transmissions were introduced by Versatile in Canada. One last feature that the combine offers are removable heads designed for distinct crops. The standard header, also known as the “grain platform,” features a revolving reel with metal or plastic teeth to cut the crop. A variation on these platforms allows for faster feeding, which reduces overall costs. Some combines even have special tracks or tires with a diamond tread to prevent them from sinking in mud. Many of these tracks can fit multiple combines since the plates are adaptable.

The combine harvester is important because it allowed for more crops to be harvested as populations increased. Farm machinery like combines allowed farms to grow, because farmers could harvest more crops. This has pushed smaller farmers out of the agricultural market, particularly immigrant and black farmers. However, combines and tractors have also encouraged overfarming, which caused the great environmental disaster of the 1930s, the Dust Bowl.

In the 1980s, electronics were introduced to measure threshing efficiency, improving grain yields by optimizing ground speed and other functions. Combine harvesters are one of the most economically important of labor-saving inventions, significantly reducing the fraction of the population that must be engaged in agriculture. As the price and necessity of combines rose in the 20th century, many small farmers lost their farms to large agricultural corporations that engage in monoculture farming, grow genetically modified foods, and require massive federal farming subsidies. While it is easy to celebrate the advances that the combine brought to American farming, it is important to also consider the damage done to the environment and economy as a result of such mechanization.

Compact Iron Stove

The compact iron stove, also known as the Oberlin stove, was invented by Philo Penfield Stewart, an American mechanic. It was patented and manufactured for domestic use in 1834. The stove had movable grates, ash sifters, hot water systems, stove top heaters, storage cupboards, and warming closets. Corrugated wood boxes, tapering fireboxes, and a few other parts of the stove allowed for more concentrated, less smoky, and more fuel-efficient fires. Additional accessories were later invented to enhance cooking and baking.

Before Stewart’s patent, most iron stoves had been intended for large industrial settings. But he felt that regular people should also be able to cook food efficiently and effectively. His compact iron stove was revolutionary as the first cooking stove to be manufactured and sold for domestic use.

Stewart’s initial design burned wood, but as coal increased in popularity, he adjusted his stoves to burn that as well. The stove was similar in size to most present-day household stoves. Its heat was produced in the main fuel-burning compartment, and a complex system of pipes and heat transfer components distributed heat to other areas. Users could therefore cook and store multiple items simultaneously, so that food could be produced more quickly and efficiently. After a few more touchups and additional improvements, the stove received prizes from the American Institute, the Franklin Institute, and the Boston Charitable Mechanics’ Association as well as endorsements from authors and other inventors.

Although the stove was popular and in high demand, it was very costly to manufacture. This

prevented Stewart from expanding his business until the Fuller and Warren stove company collaborated him. They manufactured roughly 2 million stoves. After Stewart passed away in 1868, Fuller and Warren continued to improve upon the initial design, but Stewart's natural creative spark was absent. The product's innovation and creativity slowed, causing a consistent decline in sales and popularity. Competing stoves became more popular. The Oberlin stove continued on the market, however, until the 1930s. When the Great Depression began, Fuller and Warren experienced severe declines and put an end to Oberlin stove production. It had also been made obsolete by electric and gas stoves, which were cleaner, easier, and safer to operate.

Conestoga Wagon

The Conestoga wagon or “Dutch wagon” was an 18th-century wooden freight wagon for the commercial transport of cargo. Innovative for its ability to carry and transport tons of overland freight across long distances, it was able to withstand the difficult terrain of America's eastern landscape. With its own distinctive design built by skilled craftsman with English, German, and Dutch influences and a breed of draft horses of the same name, the Conestoga was the forerunner of the cross-country long-haul freighters, and later, the covered wagon of Americans migrating west. Covering an average of 15 miles per day, the prototypes of these mammoth wagons graced America's landscape as the key transport of goods and people, contributing

toward expansion of the Western territories in the mid-19th century and carrying supplies for building the Transcontinental Railroad.

For centuries, wagons of many shapes, sizes, and capabilities dotted the towns and rural areas of colonial America. Freight wagons were designed and altered based on the topography of a particular region. The Conestoga's early origins were near Lancaster, in the Conestoga Valley of Pennsylvania, during the 1700s and 1800s. Thousands of wagons daily traversed the route between Lancaster and Philadelphia. The Lancaster Valley area settlers were of mostly German heritage and referred to as the Pennsylvania Dutch. As ranchers of livestock and operators of lumber mills, they required a reliable way to haul their goods to nearby cities and, on the return trip, to bring back produce, textiles, and manufactured goods.

The Conestoga's reputation for durability quickly spread. The earliest mention of a specific use of the “Pennsylvania farm wagon” was during the French and Indian War (1754–1763). During the Revolutionary War and later the War of 1812, Conestoga wagons were sought after by the military for hauling cannons, munitions, and supplies.

Up until this point, large freight transport had been limited to regions of the country for which wagons had been designed. These earlier wagons lacked any major ornamentation aside from paint and no mechanical braking system, relying upon the driver to rein in the horses. The Conestoga's unique design adapted to the rough terrain with larger wheels and a suspension and braking system able to withstand long distances while carrying heavy tonnage.

Predating covered wagons that utilized a flatbed rather than the concave bed of the Conestoga and seating for the driver in front, Conestoga wagons were quite different, built in accordance to the product it would be hauling and the quality of the roads. Early Conestoga wagons were smaller and capable of hauling a load of one to three tons. As roads improved, Conestogas increased in size to carry larger payloads—upward of five to eight tons.

The bed was mounted upon the four offset wheels and covered by 24 feet of homespun heavy linen or canvas tarp, which was in turn supported by up to eight

curved bows or slats of wood fanned out over the front and back openings, suggesting the sails of a ship. The canvas was rendered waterproof with a coat of beeswax or linseed oil, or combination of both, protecting the cargo from the elements.

The front wheels stood three and a half to four feet tall and were fitted with 12 spokes each. Unlike on traditional wagons, the back wheels were taller—as much as six feet in height, with up 16 spokes. This not only afforded an easier turning radius, but less power was required to pull the wagon and cargo, lessening the impact on the draft horses. The wheels were offset on their axles intentionally so that when the wagon was loaded with heavy cargo, the weight would straighten the wheels out to support it. Conestoga tires were fabricated by blacksmiths with strips of hot iron. The heated metal was cooled with water to shrink it to fit around the wooden wheel, creating a solid tire.

Supplies needed for the often arduous journey to keep the wagon fit for travel included an ax to clear debris off the road, a tool box, a feed box for the draft horses, tar, a bucket for water, and a bucket of animal grease for the wheels.

The cargo hold was made of local hardwood, usually hickory, oak, or locust. It was painted blue and enclosed with four sides 10 to 16 feet in length, all reinforced with iron straps. The cargo hold was one of the key distinctions between the common freight wagon of the day and the Conestoga. It sloped toward the middle in a slight U shape intended to keep freight from sliding out. An Conestoga feature included an iron lever brake that, when pushed by the teamster, shoved blocks of wood against the wheels to slow the wagon down rather than relying solely upon reining in a large team of draft horses.

Early Conestoga wagons were pulled by horses of the same name, a specially bred draft horse of mixed stock, possibly sired by a Flemish stallion on a Virginia mare. Teams of six draft horses, massive in size at 16 hands high or taller and weighing over 1400 pounds, pulled the equally imposing wagons. These herculean animals pulled upward of eight tons and were hardy enough to withstand long hauls with a reputation for easy temperament, whether traveling through bustling, noisy towns or in a caravan of other

Conestoga wagons and horses. Later, as the Conestoga wagon design was adapted toward overland travel for western migration, oxen and mules proved cheaper to feed with available prairie foliage, and they were less desirable for theft by Native Americans. Over time, the Conestoga breed died out as oxen and mules replaced the costly draft horse.

Along with the special breed of horses was the skilled driver referred to as a “teamster,” who was able to manage the Conestoga horses and wagon. Teamsters hitched up harnesses to the horses and guided the team with a single rein called a “jerk line.” At journey’s end, the team’s arrival was announced with a series of bells attached to each horse. These bells also served as warnings to passing teams that another was approaching on narrow roads and around blind corners.

Unlike the covered wagon of later years, there was no seating inside the Conestoga. The teamster walked with his team or was seated on a “lazy board” that slid out from under the left side of the wagon. The driver manipulated the jerk line and operated the Conestoga’s braking system from there. Most drivers of earlier periods had operated their wagons from the right side. Conestoga wagons, with drivers on the left, set the trend that stands today of the American driver’s side on the left of automobiles.

The 1850s saw a shift in demand for freight wagons, including the Conestoga. Locomotive railroads led to the decline of the long-haul trek of overland freighting in the eastern United States and, later, with the advent of the Transcontinental Railroad, the West as well. The Conestoga contributed to its own demise by supplying the building efforts of the Transcontinental Railroad. As increased locomotive presence in the eastern United States cut travel time, the demand for the long-haul freight wagons shifted to America’s Northwest and westward, stimulated by the discovery of gold in both Montana and California. By this time, wagon makers all over the country had adapted the Conestoga’s design and ingenuity. The demand for supplies increased demand for these hardy wagons as western migration, the Civil War, and mining continued into the 1880s, but by the 1890s, Conestoga wagons were found only in areas where railroad service

was limited. Relics of the Old West, these grandes dames of the American spirit found a new life in moving pictures, lending an authentic realism while recreating the mythic image of the Western experience for many generations to come.

Primary Document: Excerpt from John G. Abbott's Recollections of Traveling to California by Wagon Train (1852)

Although most western settlement happened after the Civil War when railroads began to stretch west, many settlers did travel west in the 1840s and 1850s by wagon train. Such travel was made possible by the use of Conestoga wagons that were large enough to move entire households. The following is an excerpt from John G. Abbott's description of his experience traveling to California by wagon train in 1852.

Our train was increased by other emigrants joining the caravan, 40 wagons and 60 able-bodied men, all well armed. The men called a meeting to consider protection and organize. My maternal grandfather, John Gaebhart, was elected captain. He was a veteran of the "War of 1812" and had fought Indians on the front under General Jackson, and knew all the tactics of war. He was cool, considerate, and a man of good judgment.

We then made our journey over the prairies and rolling hills covered with luxuriant grass. We met many bands of Indians. They were on most friendly terms, the main object of the visits to trade dressed buffalo robes and beaded moccasins for loaves of bread. They were great marksmen, taking real pride in how accurately they could shoot their bows and arrows.

Nothing happened worth mentioning until we reached the Little Blue River, now in Nebraska. One day we saw a man approaching on horseback as fast as his horse could carry him. He was much excited and said that a band of Indians had attacked a [wagon] train of emigrants a mile ahead of us, and

had stampeded the stock and crippled several women and children. Our captain called a halt and ordered a corral formed at once. A circle of all the wagons was formed and the women and children were placed inside. By this time the Indians 300 strong were approaching, waving their blackest and buffalo robes and yelling like coyotes. They were all smeared with war paint and well-supplied with bows and arrows. The women began to scream and pray, but our captain soon silenced them. He drew the men in a line, and gave explicit orders to keep cool and not to fire until he gave the word. On the Red Devils came. When they got within a few rods of us, our captain stepped out in front of them and beckoned with his hand for them to move on. They were appalled by the bold appearance of our men and proceeded without attack.

We moved up the Little Blue River about a mile, and came to the train that had been attacked. We assisted the emigrants in getting their wagons in shape and they traveled under the protection of our train.

Shortly after this our train was attacked by the dreadful disease cholera. My father was the first victim, only living a few hours. We laid him to rest where the Emigrant Road left the Little Blue River and journeyed on. The next day we arrived at Fort Kearney. The banks of the Platte River were lined with tents, and the cholera was raging at a fearful rate, people dying on every hand. One of our companions, a young man by the name of Sheckley, died that night. We buried him the next morning and journeyed on for many miles up the Platte River. The

cholera claimed many able-bodied men, women and children by the score. This prevailed for several days. You could see men and women on bended knees asking God for the mercy of their loved ones.

The road was lined with cattle and horses. Many emigrants were compelled to lighten their loads. You could see all kinds of wagons from prairie schooners to one horse buggies standing by the roadside. These frantic travelers cast away carpentry and blacksmith tools, bedding, wearing apparel and valuable books in their mad scramble to reach the Oregon Country. We lost about 30 per cent of our train.

After getting out of the cholera belt, we left the main road and moved up the creek about 10 miles for the purpose of resting the stock. Here was the home of the buffalo. You could see them in every direction, and I believe I can truthfully say that I saw

10,000 at one time. It afforded great sport for our men to kill them, but mostly supplied us with an abundance of fresh meat. We resumed our journey and passed Fort Laramie without mishap. At Green River [WY], the men had to fix up their wagons to keep water from coming in. A few days later we had several horses stolen. Thefts of this kind were common enough through this section of the country in those days. Some laid it to the Indians, but others thought the thieves were white men.

Then we arrived at the forks of the road leading to California. About one-fourth of our train left us, among them our highly esteemed Dr. Schnell, who located in San Francisco and for many years was one of the leading physicians of that city.

Corn Sheller

Corn is said to be one of the more essential crops, as it does double duty in providing food for farmers and for livestock as well fuel for stoves. The act of separating the corn kernels from their cob had been a time-consuming task that farmers had had to face from the beginnings of their reliance on the crop. On August 12, 1839, Lester E. Denison earned a patent for a machine he invented—a corn sheller—that would make the said task easier and faster.

The corn sheller, usually made of cast iron, is a machine that removes dry corn kernels from a cob. The first ones were powered by manual hand crank. The farmer would insert an ear of corn into the machine, which contained cylindrical components that stripped the kernels from the cob. The cob would drop to the floor as the kernels were collected in a neighboring container. When there was an excess of cobs or kernels, farmers could sell them for profit. The corn sheller continued to improve through advancing technology and still remains an important tool for modern-day farmers.

Corset

A corset, also known as a bodice, a pair of bodies or pair of stays, is a sleeveless garment worn generally under clothing that is designed to cinch the waist of the wearer to accentuate the figure for sexual attraction, aesthetics, or act as a barrier against physical harm. Historically worn by men, women, and even children for almost 500 years, this garment has been worn as under-clothing as well as a surface or outer garment; its purpose has cycled with fashion trends over the centuries.

The earliest mention of corsets appears in ancient Egypt. The military attire of foot soldiers included a "corselet," a sleeveless outer covering made from metal, leather, or bone sewn onto linen fabric, which covered the torso and chest and was held up by shoulder straps.

A woman wears a garment meant to slim the body and make it conform to a fashionable silhouette, ca. 1899. While some men chose to wear corsets in the 17th and 18th centuries, they were practically mandatory for women of the upper classes. (Library of Congress)

Stays, or bodices, as they were referred to in 17th-century Europe, began appearing with some regularity as an undergarment for women. They were held together with a cord threaded through eyelet holes that, when pulled together, tightened the material around a woman's body. The resulting effect was designed to slenderize the waist and minimize the appearance of breasts and the chest area, or, depending on the fashion view of the period, uplift the breasts while minimizing the waist and hip area.

The type of corsets worn outside clothing during this period often were adorned with finely detailed embroidery or were encrusted with precious stones, designed for the upper classes. Materials used to make early corsets included linen with wood or steel busks, plus a panel utilized to create a stiff posture and to flatten the stomach, all to enhance and create an hourglass shape to the figure. Later 17th-century corsets were constructed of materials such as whalebone and pot metal.

By the mid-18th century, corset design styles had shifted. They were tailored shorter and worn as an undergarment to heighten the breasts. Falling out of favor for well over a century, they returned in the mid-to-late 19th century and up to the 20th century, tailored to the fashion tastes of the day. The term “corset” began appearing between 1850 and 1870. During this era, with the introduction of elastic in the construction of the corset, the use of whalebone dropped.

Fashion changes witnessed a shorter corset style as the use of crinolines increased during the American Civil War (1861–1865). In the 1880s, postwar women's clothing designs reflected a restrictive aesthetic echoing the cultural mores regarding women's place in society. Corsets played a role in this aesthetic, confining women's figures as assuredly as the society in which the clothing was worn. As a possible reaction to such strict mores, corsets as erotica appeared in rigid Victorian America. Dress designs included bodices designed to look like corsets, suggesting that the wearer was provocatively displaying a garment normally seen only in private, creating an enticing effect.

The advent of the women's suffrage movement and health concerns over the often tight-fitting undergarment prompted 20th-century women to adopt less constricting clothing. With the advent of the brassiere designed to flatten the chest in the 1910s, the corset's purpose remained to slenderize the hips. The more restrictive long skirts and corsets of the previous era that had cinched around the waist were ultimately abandoned during the 1920s. After the social, political, and economic restrictions that American women had experienced, they sought to break free of such oppressive constraints by liberating themselves from restrictive clothing. Nonetheless, variations of the traditional corset remained a staple in women's wardrobes until World War II.

Coston, Martha (1826–1904)

Martha Hunt Coston was an inventor and businesswoman who developed a series of maritime signal flares used by the United States Navy, shippers, and maritime insurance firms. The navy made extensive use of her flares during the Civil War.

Coston was born in 1826, in Baltimore, Maryland, but moved to Philadelphia in the 1830s. At the age of 16, she married Benjamin Franklin Coston, who was already a promising inventor. The couple moved to Washington, D.C., where Coston oversaw a “pyrotechnics laboratory” for the navy. Despite his hard work and creativity, he never received the promotions or pay raises he was promised, or full compensation for the patents he secured. Years of inhaling dangerous chemicals on the job also left him in poor health. Benjamin died in 1848, leaving Coston a young widow with four children and enormous debt.

While sorting her late husband’s papers, Coston was searching for devices to potentially patent and sell. She discovered an unfinished idea for a system of signaling flares. Although her husband had left no specific recipes for her to follow, she began experimenting with various chemical compounds. With help from her husband’s navy colleagues and chemists, Coston spent 10 years perfecting flares that were bright enough and long lasting but also convenient to use, with a coded combination of colors. In 1859, Coston patented a pyrotechnic night signal and code system. The patent was actually issued in her husband’s name; she was listed as administrator of his estate. Her first customer was the U.S. Navy, and as she waited for Congress to agree to purchase her patent, she sailed to Europe, hoping to convince the Royal Navy and the French Navy to adopt the Coston Night Signals. She was forced to return to the United States prior to the Civil War to persuade Congress to purchase her patent, which it did—for \$20,000 (only half the amount she had originally demanded).

Once the Civil War began in 1861, the navy began placing large orders for Coston’s Night Signals. Unfortunately, Coston’s manufacturer—feeling patriotic—decided to close his factory, raise a regiment of volunteers, and join the army. The secretary of the navy intervened, persuading General Winfield Scott of the U.S. Army to order the manufacturer released from his enlistment so that he could reopen his factory. The crisis averted, Coston returned to Europe to promote the flares and entice foreign governments to purchase her patent. Coston continued to improve the system, receiving a patent in her own name for a twist-ignition device in 1871. She also continued to seek \$120,000 in delayed payments from the U.S. Navy for equipment provided during the Civil War. She would eventually receive \$15,000. Coston flares were soon mandatory equipment for every station of the United States Life-Saving Service. Coston died in 1904, but the company she had founded remained in business until the late 20th century.

Cowboy Hat (Stetson)

The cowboy hat, iconic headwear of generations of American cowboys, was the inspired invention of a second-generation American hat maker: John Batterson Stetson (1830–1906). Stetson forever turned the image of the open-plains laborer on horseback into a cowboy with the single most identifying piece of clothing: the cowboy hat.

Born of necessity, cowboy hats, also known as “beaver lids,” “boleros,” or “sombros,” did not start out as the version typified in American movies and television shows. Before the cowboy hat as we know it today, with cowboys coming from differing ethnic groups, their headgear usually reflected the country or

U.S. region from which they hailed. Early cowboys, also known as vaqueros, wore Mexican sombreros; an East Coast transplant might wear a Boston bowler from the Atlantic seaboard, and a coonskin hat might be the choice of a native of the frontier. Former Civil War Union or Confederate soldiers might sport a military uniform cap. That all changed after Stetson.

Before cowboy wear became a fashion statement emulated by American boys and girls and the symbol of masculinity in the imaginations of adults, it served a function for extreme conditions in another era. Like all cowboy apparel, each piece had a purpose aside from its aesthetics. Sashes around the waist helped hold up sagging britches or were used to tie the legs of a calf for branding. Bandanas, often repurposed from printed cloth flour sacks and hand sewn by the cowboy, served to mask faces during dust storms or to filter muddy drinking water.

Stetson, unable to compete with an established family of hat makers in his area, headed west during the migration after the American Civil War. While on the open trail, as legend has it, he demonstrated to his fellow travelers the process by which his family made their signature hats. With all the materials assembled—animal hair, fur, and/or wool—he set about matting it together. He then pressed the matted felt flat and shaped the pressed material over a mold, creating a basic hat design. Stetson then thoughtfully altered the crude design of prairie creation into a style especially suited to the unique needs of the men traveling upon the open range: he gave it a wide brim to shield them from harsh sunlight, a watertight crown that sat snugly upon the wearer's head and, when necessary, held water for a thirsty horse. It was not long before Stetson's unique design caught the eye of a passing cowboy and, with that, Stetson sold his first hat, christened Boss of the Plains.

Recognizing a need for his unique hats, Stetson opened a factory in Philadelphia, Pennsylvania, and between 1870 and 1970, the John B. Stetson Company produced headwear for men and, by the late 1800s, women too. Basic styles were either brimmed or not, with additional flourishes added to women's hats by the 1930s. The crease design variations in the crowns of men's hats might signify different regions of America,

but none of Stetson's hat designs was as iconic as that of the cowboy hat.

Stetson cowboy hats were the ones to wear for movie and television icons from the earliest days of silent films. Stars such as Tom Mix and Gene Autry often designed their own unique touches for their hats. Autry had a signature crease pattern with its own name: the Autry crease. Roy Rogers, too, developed his own signature crease, making his cowboy hat uniquely his own. William Boyd, a.k.a. Hopalong Cassidy, wore a big-brimmed Stetson; Roy Rogers wore an unassuming white one.

After World War II, the popularity of covering one's head declined, and the John B. Stetson Company closed its Philadelphia factory in 1971. The Stetson name, now licensed to another company, lives on, along with the iconic brand it created—and the most recognized symbol of the great American West, the cowboy hat.

Crumpler, Rebecca (1831–1895)

The first African American female physician in the United States, Rebecca Davis Lee Crumpler spent her adult life providing health care to poor blacks in Massachusetts and Virginia, who, if it had not been for her, would have had little access to professional medical care.

Crumpler was born on February 8, 1831, to Absolum Davis and Matilda Webber in Delaware. No photos or other images of Dr. Crumpler survive from her lifetime. In Crumpler's *A Book of Medical*

Discourses, she recalled that being brought up by an aunt in Pennsylvania known for caring for her sick neighbors influenced her to first work as a nurse in Charlestown, Massachusetts. The doctors under whom she served recommended that she study medicine. Crumpler attended the New England Female Medical College from 1860 to 1864, an unusual opportunity, as most medical colleges had not opened their doors to African Americans. At the age of 33, Crumpler became the first African American woman in the United States to earn an MD degree. The second woman was Rebecca Cole, who graduated three years later. For quite some time, historians erroneously believed that Cole was the first African American woman to become a doctor.

As the Medical College focused on training midwives, Crumpler's practice focused on the care of women and children among the poorest populations of former slaves. Crumpler stayed in Boston for a year and after the end of the Civil War moved to Richmond, Virginia, in 1865. With a population of 30,000, the former capital of the Confederacy, which had fought to keep black Americans in slavery, benefited from Crumpler's dedicated services. Were it not for her efforts, supported by the Freedmen's Bureau and assorted missionary and community groups, freed slaves would have been deprived of professional medical treatment. Along with other African American doctors, she confronted racism during Reconstruction, but as a woman, Crumpler was also a target of sexist beliefs that women belonged in the home, not in professions. Some white doctors ridiculed her, saying that the "MD" behind her name stood for "mule driver." This derision did not deter Crumpler.

After a year in Richmond, Crumpler returned to Boston, residing on African American-populated Joy Street on Beacon Hill with her husband, Arthur Crumpler. Rebecca Crumpler opened a medical clinic, where she again treated mainly women and children of color. She taught the basics of nutrition and prescribed preventive medicine for her patients. Crumpler gained a reputation as a selfless human service provider, treating patients in her house without bothering about fees for it. She also devoted her spare time to research and made copious notes about health care.

Crumpler relocated to Hyde Park, Massachusetts, after retirement in 1880–1881. To her mind, educating the public about health care was an important and developing field. All her medical experiences and notes were published in *A Book of Medical Discourses* (in two volumes) through the Boston-based publisher Cushman, Keating & Company in 1883. The target audience was women, whom Crumpler hoped to educate about the basics of health care for their families. The book was one of the first publications in the medical field by an African American, male or female.

After decades of being forgotten by the public and academia, Crumpler has been rediscovered. The Rebecca Lee Society, established in 1989 by doctors Sandra Maass-Robinson and Patricia Whitley, supports African American physicians by offering financial assistance and promotion of their work. The Association of Black Women Physicians commemorates Crumpler by giving fellowships in her name.

During the mid-19th century, when advanced education was not common even for white women, Crumpler graduated from medical school. Her life's work contributed toward the empowerment not only of black women but also of American women in general. Crumpler's diligence, honesty, involvement, persistence, and dedication underline her significance in post-Civil War America.

Cylinder Pin Tumbler Lock

The modern pin-and-tumbler lock was invented by Linus Yale Jr. He invented the lock for banks in 1851 and another for doors in 1863. In 1865, he invented the pin tumbler padlock. His designs remain the foundation of locks still used today.

The first tumbler locks date back as far as 4000 BC. This form of lock operates with two cylinders, one inside the other. The outer cylinder has springs that push on pins of varying lengths within the inner cylinder. While the lock is engaged, the pins are at irregular positions that cross between the two cylinders, preventing rotation. When a key with the correct teeth is inserted, it pushes the pins into a regular position, freeing the two cylinders and allowing the inner one to rotate inside the outer.

Linus Yale Jr. was born in Salisbury, New York, on April 4, 1841, and was a mechanical engineer by trade. He was a manufacturer and the cofounder of the Yale Lock Company. His father was an inventor and owned a lock shop, and Linus Yale Jr. became involved in the business in 1858. In 1860, he opened the Yale Lock Company, and in the same year, he died suddenly of a heart attack.

Dahlgren Gun

The Dahlgren gun was a piece of artillery used during the American Civil War by both the Union Army and the Confederate Army. The Dahlgren gun has many variant designs and was used throughout the war, seeing most action aboard naval vessels. There were two types of Dahlgren guns: shell guns and rifled guns. Shell guns possess a smooth bore, and rifled guns possess rifled bores that add spin to their projectiles, improving range and accuracy.

Union Rear Admiral John A. Dahlgren invented his gun after he saw an accidental explosion. Cast-iron cannon of the time tended to crack after they heated when fired and then cooled. Moreover, cast iron is brittle, making cannon with larger bores for larger cannonballs more likely to break and explode on firing. The accident he saw motivated Dahlgren to design a cannon that was safer and more structurally sound than Columbiad cannons. The most significant improvement that Dahlgren made on the Columbiad was a variation in its shape. Dahlgren guns had a characteristic “soda bottle” shape that allowed it to take more strain when the powder exploded.

Dahlgren’s first cannon variation was the IX-Inch Dahlgren shell gun. The IX-Inch became its most popular design, leading to the production of over 1,000 artillery pieces. It was the most versatile of all the Dahlgren gun models because it was lightweight and accurate, particularly compared to other artillery of the time. By 1864, more than 3,000 Dahlgren Guns were produced and actively used in the war. Most Dahlgren cannons were created at the foundries at Fort Pitt, Alger, Bellona, and West Point.

The IX-Inch Dahlgren gun has an average length of 131 inches, a bore circumference of 107 inches, and a trunnion diameter of 7.25 inches. The entire piece weighed around 9,000 pounds, and its effective range was about 3450 yards. Dahlgren gun artillery variants ranged from the 32-pounder that weighed 3,200 pounds with a range of 1637 yards to the XV-Inch “Tecumseh” that weighed 43,000 pounds and had a range of 2,100 yards.

Dahlgren rifled guns were nowhere near as popular as the shell guns, but the most popular rifled model was the 20-pounder rifle. It weighed around 1,340 pounds and saw service aboard various vessels. The largest Dahlgren rifled gun was the 12-inch rifle, weighing about 45,000 pounds. Most of the rifled gun variants produced after the 20-pounder saw little to no service due to firing issues and safety concerns.

Dahlgren was the first to incorporate the production of artillery pieces on a large scale, and eventually he created and produced howitzer artillery, rifles, and other gun pieces. The Dahlgren gun saw little to no action after the American Civil War as military technology advanced and newer, more effective cannons

were developed. Since new cannons were on the rise and the demand for the Dahlgren fell abruptly at the end of the war, it became obsolete. John Dahlgren passed away in 1870, and production of the cannons was discontinued after the American Civil War ended.

Deere, John (1804–1886) and Deere and Company

American inventor, businessman, and blacksmith John Deere founded Deere and Company in 1868. Deere invented the polished steel plow in 1837, which allowed Midwestern settlers to cultivate the heavy soil and tough native grasses of the Great Plains. Today, Deere and Company is an American multinational headquartered in Moline, Illinois. It produces agricultural and construction machinery and productivity software.

John Deere was born on February 7, 1804, in Rutland, Vermont, to Sarah Yates Deere and William Rinold Deere. After finishing his public school education, he turned his efforts to becoming a blacksmith. At 17, he took a three-year blacksmithing apprenticeship with Captain Benjamin Lawrence and in 1826, at 21, he set up his own blacksmith shop. A year later, he married Demarius Lamb, with whom he would have nine children.

With the recession of 1837 impairing his job prospects in Vermont, Deere headed west. Leaving Demarius to look after their then five children, Deere went to Illinois and settled in Grand Detour. He set up another blacksmith shop and a year later sent for Demarius and the children. He repaired the cast-iron and wooden

John Deere, who founded Deere and Company, developed a steel plow in 1837 that could scour the heavy western soil of the United States, which allowed farmers to plant considerably more acreage. (Deere and Co.)

plows of the local homesteaders. The plows were imports from the eastern states, which had soft, sandy soil, and so they were ill suited for the dense, rich, and clay-infused Illinois soil. The soil would stick to the blades, requiring farmers to continually stop and clear them. The blades would also break after getting stuck in matts of roots and mud. Deere's solution was to design a steel-bladed plow. Unlike an iron plow's, the smooth, steel blade easily scythed through the soil.

The plow proved immensely popular. To capitalize on its success, Deere formed a partnership with Leonard Andrus to set up a factory. By 1846, they were producing 1,000 plows a year. But that same year, the partnership fell apart, and Deere moved to Moline, Illinois, a transportation and trade hub on the Mississippi River. Deere built a new factory, and by 1855, he was producing 10,000 plows a year. In 1857, Deere entrusted the day-to-day running of the company to his son Charles but remained president until his death.

Production increased, and the company began producing other farming equipment, including wagons, corn planters, and cultivators. In 1863, a sit-down cultivator was introduced: the Hawkeye Riding Cultivator. Deere received his first patent in 1864 for the molds used in casting his steel plows. In 1875, he introduced the Gilpin Sulky plow. It was horse drawn but with a seat. Three years later at the Paris Universal Exposition, it beat 50 other plows in a field trial. The next year, the plow sold over 5,000 units. In 1881, Deere inaugurated the first factory in the United States to be lit by electricity in Rock Island County, Illinois.

Demarius Deere died in 1865, and John Deere married her sister, Lucinda, two years later in June 1867. Deere was mayor of Moline from 1873 to 1875. He died May 17, 1886, at the age of 82. Deere's company lives on well after its founder's death.

At the beginning of the 20th century, the company began producing petroleum-powered tractors, the first of which was the Dain All-Wheel-Drive tractor. Deere continued to expand into gasoline-powered tractors by purchasing the Waterloo Gasoline Engine Company of Waterloo, Iowa. In 1919, Deere sold 5,634 of its new Waterloo Boy line of kerosene-powered tractors. It introduced the first combine harvester in 1927, the first machine that could reap and thresh grains at once—reducing the time it took farmers to harvest their crops, greatly improving productivity. The company introduced the Model A and B tractors in 1934 and 1935. 1935 saw the introduction of the D1, a heavy-duty tractor for industrial use. In 1937, the centennial of the company saw revenues reach 100 million.

The company's contribution to the war effort during World War II was extensive. Charles Deere Wilman, the president of the company at the outbreak of World War II and the great grandson of the founder, accepted a commission as an army colonel. He also directed the farm machinery and equipment division of the War Production Board during the war. Around 4,500 employees of the Deere company joined the army in their own battalion. The company produced military tractors, aircraft parts, ammunition, and mobile laundry units. To produce M3 Lee and M4 Sherman tank transmissions, Deere set up a separate company, Iowa Transmission Company, at their

Waterloo Works production site. However, wartime limitation orders reduced output and what they could build. The office of production management ordered manufacturers to build at only 80 percent of 1940's production level, but they could build spare parts to keep old tractors running.

In 1947, the model "M" tractor was built at the new John Deere Dubuque Works. Two years later it became a bulldozer when designers added a front blade and named it the "MC."

This is the first of its construction equipment. The 1950s were a time of expansion. In 1956, the company bought Lanz, a German tractor and harvester maker. 1958 saw the introduction of its industrial equipment division that focused on industrial application, a turn away from Deere's agrarian equipment past. The 440 crawler was its first product. Its consumer equipment division for lawn and garden tractors and mowers was introduced in 1963. The company now produces planters, buggies, wagons, grain drills, and hay and harvesting equipment.

John Deere is the largest agriculture machinery company in the world, with production facilities in the United States and 17 countries, including China, Germany, and Brazil. It employs 67,000 people worldwide and has a valuation of over \$40 billion on the New York Stock Exchange, with revenue of over \$26 billion in 2016. Today, Deere and Company offers an extensive variety of machinery for lawn care, landscaping, agriculture, construction, and forestry, and it builds engines and productivity software. Its portfolio consists of tractors, combines, mowers, sugarcane harvesters, planters, grain harvesters, loaders, dump trucks, backhoes, dozers, excavators, and tree fellers.

Dental Chair

Dental chairs play an important role in operative dentistry. The first commercial dental chair was developed and patented by Milton Waldo Hanchett in 1848. Previous such chairs had often been designed and built by dentists themselves, mostly from household armchairs; they differed only slightly from ordinary rocking chairs. Some of the first attempts to improve them included the addition of a headrest, at first fixed and then movable, followed by the ability to change the height of the seat, and then the positions of both the back and the seat.

Milton Waldo Hanchett (1822–1904) of Syracuse, New York, developed and patented the first dental chair that combined all of these improvements. He was granted U.S. patent number 5711 on August 15, 1848, for a “surgical or dental operating chair” with adjustable elevation and tilting seat and back. It had a central supporting screw under the seat by which it could be raised or lowered similarly to a piano stool. The seat hinged in such a manner that it could be tipped forward and backward and held in a particular position. Elevation was accomplished by turning the seat on the screw, which was fixed to the seat by gudgeons at the ends of horizontally projecting arms, making possible the tipping of the seat forward and backward. The chair also had a footrest that could be elevated and at the same time brought nearer for the convenience of the patient. The entire chair was held in the desired position by means of notched iron semi-circles and a cogged wheel controlled by a winch and ratchet.

Hanchett’s dental chair was never put into production, but other dental chairs with the same design were subsequently manufactured. Hanchett’s chair, in effect, was a prototype for the commercially manufactured dental chairs from F. Searle of Springfield,

Massachusetts, in 1849. They had seats that could be adjusted vertically by a series of hinges. By tipping the seat on the front hinges, it was inclined forward, and the reverse movement was secured by the back hinges; when both hinges were operated, the whole seat could rise vertically. The different positions were attained and held by way of cogged iron quadrants. Another dental chair invented and manufactured by C. H. Eccleston from Utica, New York, had the seat positioned on steel springs that were held in place by tightening a setscrew on a retaining rod. The back of this chair, however, could be tipped forward and backward on a hinge pin exactly the way described in Hanchett’s patent. There are several other examples (including by Perkins, J. O. Whitcomb, Ask, Archer, and S. S. White) illustrating the rapid progress of the product before the implementation of hydraulic mechanisms in the modern reclining dental chair.

Detachable Collar

A collar that can be taken off a shirt and reattached is a detachable collar. It started as a simple way to save time and energy for 19th-century housewives but became a common fashion accessory for 100 years.

Hannah Lord Montague (1794–1878) lived in Troy, New York. Her husband was a merchant and manufacturer of quality women’s shoes and a respected businessman who wore a clean shirt to work every day.

Montague was responsible for the household chores, which included laundry. Laundry in the early 19th century was definitely a chore: there were no washing machines. Water collected from an outdoor pump in a wooden bucket filled a cast-iron pot on a cookstove. The stove required wood or coal for its fire. The dirty clothes were soaked in the hot water and

then rubbed on a washboard (a rectangular wooden board with ridges). Another bucket or two of clean water was needed to rinse the clothes. Clean clothes were hung on a line to dry. It could take more than a day to wash laundry, depending on weather. Once dry, clothes such as men's shirts were then starched and ironed. Laundry was a long process.

In 1827 Montague noticed that the collar and cuffs of her husband's shirts were dirtier than the rest of them. Repeatedly washing the entire shirt seemed unnecessary. Shirts were expensive, so Montague had an idea. She cut the collar off her husband's clean shirt, sewed tape at either end of the collar, and reattached it to the selvage (a fabric's edge woven so that it doesn't fray). The next time she did the laundry, she took the collar off the shirt; washed, dried and starched the collar; and reattached it. Since the shirt itself could be laundered less frequently, it could be replaced less often, saving money. When a collar got discolored and had to be replaced, it was cheaper to buy than a shirt—about 35 cents.

There were many styles of detachable collar over the years. Some were secured with string or tape wound around the wearer's neck, but these could loosen and separate from the shirt. Other styles of detachable collars were more secure because the collar reattached with studs, pins, or buttons.

Fashionable men at the turn of the 20th century still wore detachable collars. It wasn't until after World War I (1914–1918) that fashion became more relaxed and men wore shirts that were made of softer material and had attached collars.

Dix, Dorothea (1802–1887)

American activist Dorothea Dix fundamentally altered the American approach to treating the mentally ill. She also worked as the superintendent of army nurses during the Civil War. Dix excelled at organizational innovation for health care institutions.

Dix was born April 4, 1802 in Hampden, Maine, to Joseph Dix and Mary Bigelow. At the age of 12, she moved in with her wealthy grandmother, Dorothea Lynde, in Boston to get away from her alcoholic and abusive father. In 1821, Dix opened a school that was paid for by well-to-do families. After opening her school, she also began teaching poor children out of her own grandmother's house until poor health forced her to stop.

Dix next worked as a governess. While working for a family, Dix traveled to St. Croix and witnessed slavery there. Dix was appalled by slavery and vowed to work to end it. In 1836, she took a trip to Europe to mend her health. While there, she met other reformers who inspired her viewpoint on equal rights, specifically equal rights for the mentally ill. She spent some time with English Quakers who believed that the government should play a direct, active role in social welfare, including the care of the insane.

After returning to the United States, Dix led an investigation into those people classified as the insane poor in Massachusetts. This investigation showed that in most cases, towns worked with local individuals to care for the mentally ill who could not care for themselves and had no family to do so. Dix saw that the mentally ill were completely dependent on private individuals, which resulted in widespread abuses. In 1844, she investigated "insane asylums" and recorded the conditions in which the mentally ill were kept and the treatment they received. Her report exposed the systematic mistreatment of asylum patients.

In her investigations, she found a man who was a respected legislator and jurist who had become mentally insane in his old age. Dix had found him lying on a small bed in a basement of a country house, absent of necessary comforts. Her discoveries resulted in a bill that expanded the state's mental hospital to provide for more mentally ill people. Many members of the legislature knew the old man she had found, and in response, Joseph S. Dodd introduced her report to the state senate, which in turn authorized an asylum.

After this victory, Dix continued her investigation, traveling from New Hampshire to Louisiana and making reports to send to state legislatures and working with committees to pass bills. When Dix moved on to Illinois in 1846, she fell ill, and her investigation was temporarily put on hold. When she sent a report in January 1847, legislation was adopted to establish Illinois's first mental hospital. She continued visiting different states, calling for reform in the care of mentally ill patients.

In addition to being an activist for the mentally ill, Dix also served as superintendent of army nurses in the American Civil War, narrowly beating out Elizabeth Blackwell, the first American female doctor, for the job. At the time, nurses were not respected health care workers. In fact, female nurses were often equated with sex workers. Dix required female volunteer nurses to be plain or unattractive, 35 to 50 years old, and to dress in unadorned, dark clothing. Three thousand American women served as army nurses during the Civil War. Dix's contributions to the professionalization of nursing lay in her great talent for organization and her insistence that nurses be treated as respectable women.

Dix was also widely admired but also criticized for her insistence on treating Confederate soldiers. After Gettysburg, for example, the Confederate Army withdrew, leaving over 5,000 wounded soldiers behind. Dix and her nurses treated these men, as well as Union soldiers, on the principle that suffering men required moral treatment regardless of their personal circumstances.

After the war, Dix helped fundraise for a monument to honor the soldiers lost at Fort Monroe. She traveled the United States to review the asylums and prisons she had helped create to evaluate the damage of the war. She died on July 17, 1887, and was buried in Cambridge, Massachusetts.

Camille Michaluk

Dorothea Dix is best known for her work on behalf of the mentally ill and for serving as a superintendent of army nurses during the Civil War. For all her contributions, a crater on Venus was named Dix in her honor in 1994. (Library of Congress)

Double-Barrel Cannon. See Cannon, Double-Barrel

Dustpan

Most people rarely think about common, everyday household items such as the dustpan until they actually need them. The issue of what to do to transfer all the dirt, dust, and trash that was gathered by a broom into the garbage can would not be solved until the late 1850s.

On July 6, 1858, inventor Thomas E. McNeill earned a patent for the first dustpan, though African American inventor Lloyd P. Ray is associated with improving the product. On August 3, 1897, Ray earned a patent for his version, which addressed two immediate issues at hand: efficiency and the need for one to be on hands and knees to sweep the dust into the pan. Ray's version collected more dust and had a long handle. Varying patents of the dustpan came after, but Ray's is still said to be the basis for others.

Eggbeater

Ralph Collier of Baltimore, Maryland, patented the rotary eggbeater in 1856. He designed his labor-saving kitchen invention to froth, whip, and beat eggs. Collier, a tinsmith by trade, and Alfred H. Reip, a fellow tinner and ironware manufacturer, jointly produced the tin-wire, handheld eggbeater tool. It worked when one turned a handle on top of vertically revolving gears. Collier's eggbeater revolutionized the baking industry. Prior to the invention of his eggbeater, spoons had been used to whip eggs. While this was fine for omelets, it was necessary to whip eggs properly, especially egg whites, to ensure the taste, texture, and density of baked goods.

Collier's eggbeater served as a catalyst for future eggbeater designs. British inventor E. P. Griffith's included a handle with vertically revolving gears inside of tin can. He claimed that his product equaled 288 strokes of a spoon with every turn of the tool's handle. The Dover Stamping Company redesigned the

eggbeater and marketed it as a pattern-improved tool. It became so popular that the U.K. business manufactured over 4 million of the mechanical, handheld eggbeaters popularly known as Dovers. The Dover eggbeater had the company name stamped on its mechanical gear and came with a warranty. It could be purchased in family size, hotel size, and an extra family size; on average, it cost \$1.25.

African American Willis Johnson of Cincinnati, Ohio, expanded the size of the eggbeater design with his patented rotary beater machine. His dual-acting device was an early mixing machine intended for eggs, batter, and any other ingredients necessary for baking. The Johnson hand-cranked mechanism allowed baking on a large scale; its main frame contained a driving wheel, pulley, and two cylinders. The cylinder chambers, which were equipped with spring-like whisks, could be used for two different mixtures, such as batter in one chamber and eggs in the other. Conceivably, a baker could also clean one chamber while using the other to beat an ingredient.

American engineer Herbert Johnson, working for the Hobart Manufacturing Company, took the eggbeater one more step by redesigning it as a bread dough device for wholesale bakeries. The Hobart design became an electric, free-standing commercial mixer with an 80-quart capacity. The popular kitchen appliance, which eventually became known as the KitchenAid Food Preparer, remains a standard. Ivar Jepson, an inventor working for Sunbeam Products, completed the 19th- and 20th-century evolution of the eggbeater when he invented the Sunbeam Mixmaster. Jepson's eggbeater utilized two detachable blades that interlocked when electrically operated. The Mixmaster was a mass production success for Sunbeam, even though it debuted during the Great Depression. Today, this easy-to-use electric mixer can still be found in numerous modern kitchens.

Electric Doorbell

The electric doorbell was invented in 1831 by Joseph Henry (1797–1878), an engineer and inventor. The first electric doorbells were simple buzzers; bell chimes were not introduced until the early 1930s.

While experimenting with electromagnets, Henry discovered that he could use several small batteries and produce enough power to send a signal down a length of wire. Henry ran more than a mile of wire around the upper rooms of the Albany Academy and succeeded in using his electromagnet to ring a bell.

The first electric doorbells were battery operated. By 1896, a homeowner could order a doorbell kit from the Sears catalog for as little as \$2.50, which included the bell (actually a buzzer), a push button, battery, wire, and assorted hardware for installation. Batteries were gradually replaced by transformers once homes became connected to the electric grid, and by the 1920s, transformers were increasingly affordable to homeowners. The first musical doorbells were introduced in the mid-1930s and were marketed as luxury items.

Electric Stove

William Hadaway patented the first electric stove in 1897. The electric stove gradually replaced wood and coal stoves in the early 20th century.

In 1859 George Simpson patented the first electric coil system, which he theorized could be used for cooking. An early electric stove appeared at the Chicago World's Fair in 1893 as part of an electric kitchen demonstration. Hadaway's patent four years later improved upon the World's Fair stove by including knobs for automating and controlling heat. The 1920s

and 1930s rural electrification movement increased demand for electric stoves, which were considerably easier and cleaner to operate than wood- or coal-fired stoves.

Electric stoves relied on heating coils until the early 21st century, when solid-state electric cooktops became more widely available. Induction cooktops, which heat through electromagnetic induction, further innovated electrical stoves. Today, many home cooks and most commercial cooks prefer gas stoves, but the electric stove continues to command a significant market share.

Electric Street Railway

The electric street railway is based on railway tracks, generally in urban areas. Each is known by a different name, depending on the region. The railways are electrically powered, usually by wires that run overhead. The wires are connected through sliding grips to the tops of the vehicles. The sliding grips are called “pantographs.” They are designed for low friction when in contact with the sliding wires, preventing wear that could cause them to break and leave the vehicle with no power.

Electric street railways have been a popular method of transportation for short distances within cities since the 1880s. The first street railways, also called omnibuses, were pulled by horses. The next versions were steam powered and used the same engines that locomotive trains did, only smaller. Then they became cable-pulled cars, which could be lighter because now they did not have to support the weight of steam engines. These cars were connected to a station

with a cable that pulled it along the tracks. After that, the cars became electrically powered.

Electric street railways have their own railway systems and dedicated lanes in cities. When electric street railways started to appear in Saint Petersburg, Russia, there were two types: battery powered and one with an overhead powering system. The second type became more popular due to its reliability. Electric street railways were popular in urban areas because they were easier to build, maintain, and run than conventional trains. Also, because they ran within cities, they had to be light. They were therefore cheaper than railcars for traditional trains.

The first electric street railway system in the United States was built in Cleveland, Ohio. By 1900, there were already close to 900 electric street railways in the country. Electric street railways were the most popular method of transportation for a few decades until the 1930s, when the Depression hit the United States. When the automobile industry expanded during the 1940s, electric street railways fell behind.

Electric railways declined in part because of the large infrastructure investment they require. An electric street railway must have a dedicated lane on streets, since they operate on rails. Also, in some cities, petroleum companies bought the electric railway companies and closed them down to encourage people to buy cars. Despite that, electric street railways still operate in many cities, including San Francisco, Boston, Cleveland, Philadelphia, Pittsburgh, Newark, and New Orleans, where they enjoy significant popularity

Elevator Safety Brake

“All safe.” With those words, Elisha Graves Otis (1811–1861) did two things: he calmed the astonished onlookers at the 1853–1854 New York World’s Fair after he had cut the rope suspending the platform where he had stood—and he also ushered in the modern urban skyline. He accomplished both with his introduction of the elevator safety brake.

Elevators themselves were not exactly a new invention. Devices for raising and lowering people or freight had been noted as far back as the ancient Greek engineer Archimedes (ca. 287–212 BCE). Improvements took place steadily throughout history as elevator platforms were suspended by pulleys on ropes or chains and powered by humans or animals. Steam power was utilized in elevators for hoisting coal or lumber in England’s Industrial Revolution during the first half of the century. In 1823, two enterprising London businessmen offered an “ascending room” in which paying customers could be carried high enough to observe a panoramic view of the city below.

What Elisha Otis’s demonstration proved was that a safety feature could successfully engage even if an elevator’s cable broke. In his safety brake, a metal wedge was jammed from underneath the elevator car into a channel in the guide rails if the car started to descend too rapidly. The friction between the wedge and the rail continued to build until it ultimately brought the elevator car to a stop at a comfortable rate.

The demonstration was so successful that sales of Otis elevators rose along with the equipment his company built. With his factory in Yonkers, New York, Otis was able to supply elevators for the mushrooming construction of Gilded Age skyscrapers in nearby New York City. This changed the way people lived and worked. Before this invention, richer tenants had lived in street-level apartments and poorer ones lived on higher floors, where it was more difficult to carry groceries and other products. Once elevators could be trusted, apartment buildings grew taller, and richer

tenants opted to enjoy the view from private penthouses while poorer ones were relegated to street-level apartments with all their noise and dirt. New York's seven-story Equitable Life Building, completed in 1870, was the first office building to utilize passenger elevators.

New York was also the site of the first buildings to showcase Otis's groundbreaking technology called "signal control," a system allowing the device to operate without human intervention. Signal control was introduced in 1924 in New York City's Standard Oil building. It allowed the doors to self-close, and passengers pressed keys for their desired floors, just as we do today.

Otis elevators, reliable because of their revolutionary safety brake, became a key component in the history of New York's iconic Empire State Building. When the structure was being constructed in 1931, Otis elevators made it possible for the building to reach its full height, including the observation deck on the 86th floor.

Company representatives still state that with the safety brake, elevator accidents are extremely rare. Many elevator accidents actually occur due to human error or negligence, as in 2011 when a New York City office worker was crushed to death when the elevator car surged upward with the door still open. The investigation showed that maintenance workers had disabled safety equipment during repairs and had neglected to reset the system.

Today, the Otis Elevator Company remains the largest maker of elevators in the world, providing and maintaining almost 2 million units in 200 countries around the globe. Otis elevators are in the world's tallest buildings, essentially making them possible. The company runs a 29-story testing tower at its research center in Connecticut. According to the corporation, its testers still use the words of the company's founder, Elisha Otis, when he confirmed that his revolutionary safety brakes had worked: "All safe."

Equatorial Sextant

Sailors used compasses to navigate the world's oceans for centuries. Determining north could be just as tricky on water as it was on land. Sextants were invented in the 18th century to improve navigation, but like any mechanical device, they were only as accurate as the individual who used them. William Austin Burt (1792–1858) improved the accuracy of the compass in 1836 when he invented the solar compass, and 20 years later, he improved the accuracy of navigating the ocean with the equatorial sextant.

Burt's solar compass was one of the exhibits at the Great Exposition's Crystal Palace in London in 1851. Traditional compasses determined north by orienting to magnetic north, but their readings were not always accurate due to interference from large ore deposits and fluctuations in the earth's magnetic field. The solar compass did not have these problems. It determined north by orienting to the sun. Therefore, it was accurate in any location.

Burt's voyage from the United States to England to display the solar compass at the first World's Fair took weeks. The ship he traveled on went off course several times while crossing the Atlantic. Burt's round-trip voyage gave him an idea of how to adapt the sextant to plot ocean navigation more accurately.

The word "sextant" refers to a one-sixth arc of a circle, or 60 degrees. The sextant as a navigation tool is a handheld device with a 60-degree arc scale at the bottom. It has two mirrors, an adjustable arm, and a sight. The sight is a tube that resembles a small telescope. Facing the horizon, one looks through the sight at two mirrors. One mirror is half silver and half clear. The ocean horizon is viewed or sighted through the clear half of this mirror. Light from the object being sighted, the sun, reflects off the other mirror. This mirror is attached to a movable arm or lever. The moveable arm

is adjusted until the two images, horizon and sun, are in the same field of view. The reading on the scale is the angle between the sun and the horizon. This reading and the time of day of the observation (recorded in hours, minutes, and seconds) is then compared to a nautical reference chart. After solving some mathematical equations, one obtains the ship's latitude. Since the sun's angle of movement across the sky changes from season to season, calculations may have to be adjusted based on time of year. Sextants can be used at night. A star, such as Polaris, the North Star, is used for sighting.

Burt's sextant eliminated the need to consult a nautical chart. The equatorial sextant is an ordinary sextant with several adaptations attached. The main body or frame of the instrument is the meridian circle, which rotates on a spindle. All other measurement circles or arcs are directly or indirectly attached to this circle. There is a latitude circle, an hour circle, an azimuth circle, a declination arc, and an altitude arc. Azimuth, altitude, and declination determine a celestial body's location.

To use the equatorial sextant, the user sets a given latitude on the latitude circle. Then the declination arc is set as well as the time of observation. Without consulting any chart or completing a mathematical calculation, the user can read the altitude, azimuth, declination, latitude, and time on the sextant.

Burt received a U.S. patent in 1856 (patent number 16,002), and he patented the equatorial sextant in France, Belgium, and England in 1857.

This one device supplied the navigational information provided by a regular sextant and charts with no calculations required. Burt spent the last two years of his life promoting the equatorial sextant and died in 1858.

Field, Cyrus West (1819–1892)

Cyrus West Field, a successful American capitalist and financier, was instrumental in the laying of the first transatlantic telegraph cable. Field was born into a long-established New England Puritan family (with American roots perhaps as far back as 1629) in Stockbridge, Massachusetts, in 1819. Rather than pursue a higher education as did his three brothers—a well-known minister, a U.S. congressman, and a Supreme Court justice, respectively—Field joined the business world in his early teens. After trying his hand in a few different arenas, Field capitalized on new innovations in mass-market publishing and made a fortune in paper manufacturing. It would not be the last time an investment in new technology would pay him dividends. Because of his success, he was able to retire at age 34. After his retirement, Field focused his energies on philanthropy and investment, and he built a new career as a financier.

Throughout the 1830s and 1840s, a number of individuals had been developing electromagnetic technology that would create the telegraph. Samuel F. B. Morse's model was the most successful. After Morse invented his telegraph, though, he struggled to generate capital for laying cable. His line between Baltimore and Washington transmitted its first message in 1844, and soon, telegraph lines, laid by a number of competing companies, spread over the eastern United States and reached California by 1861. Despite much effort and multiple strategies, though, Morse had yet to accomplish the goal of connecting Europe and the United States via telegraph.

Field took an interest in this project. He invested his own money, and, even more important, he worked to secure funding from governmental and private sources as well as the services required for laying the cable. To these ends, Field partnered with Englishmen John Watkins Brett and Charles Tilston Bright to found the Atlantic Telegraph Company on November 6, 1856. They sold shares to investors and soon accumulated enough money to undertake the project.

The most significant obstacle preventing the linking of Europe and the United States, other than generating the money to do it, was a practical one. Laying cable over land was difficult enough, and the

process was developed only in fits and starts, but laying undersea cable was a tremendous feat of engineering. Bright was the leading engineer of the project, and he, Field, and others worked together to devise the best method for laying cables that would be protected, durable, and also, if possible, inexpensive. They also needed to find the most efficient route. There is a natural plateau between Newfoundland and Ireland where the ocean is shallower than in most parts, and here they decided to lay the cable. Also, Brett had already been involved in these plans, through the by-then-defunct Newfoundland Telegraph Company.

Beginning in 1857, the Atlantic Telegraph Company made several attempts to drop cables, the first three of which failed due to breakage. In 1858, a message was successfully sent across the ocean, but the cable was not sustainable and needed constant repairs. After three weeks, it was no longer operational. Field had some trouble generating more funds, especially from the U.S. federal government, given its involvement in the Civil War. In 1866, Field founded the Anglo-American Telegraph Company to recover some of the failed cables for repurposing and to lay new cable. That year's expedition, led by the steam ship *Great Eastern*, was finally successful.

Later in life, Field invested heavily in stocks, especially those of railroad companies. He increased his fortune and became a great patron of the arts, financing artists' endeavors and donating money and art to museums. However, toward the end of his life, he lost much of his money in futures speculation when the wheat market went under in the late 1880s. Field died on July 12, 1892.

Fire Alarm Call Box

A fire alarm call box is a signaling apparatus designed for public use during fire emergencies. Call boxes are typically of cast iron and are mounted to utility poles or atop a pole. Modern call boxes have pull levers that can be directly operated by anyone, but earlier systems required a key holder to operate.

The fire alarm box was the creation of physician and inventor William Francis Channing (1820–1901) and electrical engineer Moses Gerrish Farmer (1820–1893). Channing was aware of Samuel Morse's (1791–1872) telegraph system and had the idea that it could be put to use as an alarm system.

Channing sold the idea of an alarm system to the city of Boston. On April 28, 1852, the first municipal fire alarm telegraph system was put into operation. It consisted of 40 call boxes and 16 alarm bells, all coordinated at a central Fire Alarm Office. To operate the alarm, a person had to open the box and turn a hand crank, which would send a telegraph signal to the central office that indicated the call box's location.

In 1855, South Carolina postmaster and telegraph company agent John Nelson Gamewell (1822–1896) was attending one of the frequent lectures presented by Channing on the fire alarm system. Gamewell was intrigued and purchased regional rights for marketing the system. On May 19, 1857, Channing and Farmer received a patent for their alarm system, and in 1859 Gamewell purchased all rights to the system.

During the Civil War, Gamewell returned to South Carolina. His patents were seized by the U.S. government and set to be auctioned off to the public. A company employee, John F. Kennard, was sent to Washington to bid on the patents and managed to win them back for only \$80.

In 1879, Gamewell reorganized his company, calling it the Gamewell Fire Alarm Telegraph Company. By the end of the century, Gamewell fire alarm systems were installed in more than 500 cities throughout the United States, including San Francisco (1865) and St. Paul, Minnesota (1873).

Because fire alarm call boxes are publicly available, they have often been abused for false alarms. A variety of remedies have been suggested for eliminating these, including a shed that locks behind a caller and a hare-brained approach that sprang a set of handcuffs on one.

Today, even with the ubiquitous cell phone, some cities have opted to keep their fire alarm boxes in use as part of a redundancy measure. The systems have proven themselves reliable during emergencies, and because the fire calls do not have to be routed through a dispatcher, there is no chance for language miscommunications.

Floating Dry Dock (1849)

Abraham Lincoln (1809–1865) accomplished many things in his lifetime. He was a self-taught man who worked a variety of manual labor jobs while studying in his free time. He loved books and learning, but he was very practical. If he encountered a problem, he solved it. One problem's solution led to an invention, and Lincoln is the only president of the United States to hold a U.S. patent, which he held for the invention of the floating dry dock.

Lincoln was born in Kentucky and grew up in Indiana. His family moved to Illinois in 1830. When Lincoln was a young man, he worked as a flatboat operator and hired hand on riverboats. A local businessman hired him to take merchandise from Sangamo Town, Illinois (north of Springfield), to market in New Orleans, Louisiana, in 1831. The water route was via the Sangamon River and the Illinois River to the Mississippi River.

Lincoln and another man loaded hogs and barrels of corn, bacon, and pork on a flatboat. The heavy boat ran aground on a milldam, with its front hanging over the dam while its back end slowly filled with water. Unable to force the boat over the dam, the men unloaded the hogs and cut a small hole in the bottom of the front part of the boat hanging over the dam. They moved some of the barrels to the front of the boat, and this redistribution of weight caused the boat to tip and the water to drain out the hole in the bottom.

The men plugged the hole, reloaded and redistributed the cargo, and the boat was able to float again.

Years later, Lincoln saw another boat grounded. That boat's crew used empty barrels to free it by forcing them under the boat's sides, which lifted it enough for them to move it. This method did not require taking cargo off the boat or redistributing it, and it gave Lincoln an idea. He invented a device that was fitted to the side of a boat just below the waterline on each side. It consisted of inflatable chambers, made of rubber cloth or similar waterproof material, that were attached to the boat. If a boat went aground, all or some of these chambers could be inflated using a bellows system or a steam engine. The inflated chamber(s) would lift the boat higher than what it was stuck on it could float freely again. When the chambers were no longer required, they would be deflated and repacked until needed.

Lincoln made a model of a boat with the device attached and applied for a patent. Though he was a lawyer, he hired patent attorneys to help process the application. The buoyancy device received patent number 6,469 in 1849.

The device was clever, but it had its drawbacks. One criticism was that other methods were available to free grounded boats, so the device was unnecessary. Another was that it would be expensive to install and

to maintain. Also, a lot of force was needed to inflate the chambers to raise a heavy boat over an obstruction. Plus, the chambers added weight to a boat and so might even cause the problem they were designed to fix.

A workable buoyancy device based on Lincoln's design was never produced, although his idea had merit. The idea of buoyant chambers was a precursor to those that engineers used when designing submarines. It was also similar to the process used by ship salvagers to refloat sunken vessels.

Lincoln was a man of many talents and is best remembered as president of the United States (1860–1865), member of Congress, a politician, and lawyer. Now inventor can be added to his list of accomplishments.

Primary Document: Excerpt from Abraham Lincoln's Patent Application for the Floating Dry Dock (1849)

In 1848, Abraham Lincoln traveled between congressional sessions from Washington to Illinois. Along the way, the flatboat he was traveling on was stuck on a sandbar. Lincoln watched as the crew used empty casks and boards to force the boat back into the water. This incident started him thinking about a floating dry dock apparatus that might be used to prevent just such a thing. His invention was never implemented, though he did have a scale model of it made. The following is an excerpt from Lincoln's patent application submitted by his patent attorney in March 1849. Lincoln was issued Patent No. 6,469 on May 22, 1849.

Be it known that I, Abraham Lincoln, of Springfield, in the county of Sangamon, in the state of Illinois, have invented a new and improved manner of combining adjustable buoyant air chambers with a steam boat or other vessel for the purpose of enabling their draught of water to be readily lessened to enable them to pass over bars, or through shallow water, without discharging their cargoes;

What I claim as my invention and desire to secure by letters patent is the combination of expansible buoyant chambers placed at the sides of a vessel with the main shaft or shafts C by means of the sliding

spars or shafts D which pass down through the buoyant chambers and are made fast to their bottoms and the series of ropes and pullies or their equivalents in such a manner that by turning the main shaft or shafts in one direction the buoyant chambers will be forced downwards into the water and at the same time expanded and filled with air for buoying up the

vessel by the displacement of water and by turning the shaft in an opposite direction the buoyant chambers will be contracted into a small space and secured against injury.

Gas Well

Natural gas has come to dominate the American energy market, surpassing all other sources in recent years, and it all started with a single man in Fredonia, New York. For years, people had theorized, experimented, and told stories of natural gas that could be used for energy, but none of these were serious scientific or business inquiries. This all changed when an uneducated tinsmith named William Hart decided to take these stories and turn them into a commercial venture through the drilling of natural gas. While it is debated who first discovered natural gas, Hart was the first to successfully create natural gas wells and provide the energy directly to buyers.

In 1825, William Hart drilled his first gas wells in Fredonia, New York. The local paper originally reported that the drilling had been done in slate, but it was, in fact, in shale. Within months, the gas wells were providing the energy needed for lights in two shops, two stores, and a mill. The gas was stored in a gasometer, another Hart creation, and was transported to the shops through wooden pump-logs that were covered in tar-laden cloth at the joints. Hart's wells drilled into shale, which is a major source of natural gas. Gas in shale is accessed through fractures in the rock. These fractures allow gas to flow freely, which can then be collected and used as energy.

While the acquisition of natural gas first began with Hart, natural fractures had to be found to access the gas, which meant that there was very little available, making other energy sources, like coal, not only more practical but more profitable. With the profits of coal and later oil, natural gas remained a secondary source of energy

for much of American industrialization. The invention of hydraulic fracking changed the natural gas industry dramatically. With hydraulic fracking, more of the gas stored in shale could be accessed by creating artificial fractures that allowed the gas to flow. With both the technique of fracking and the discovery of vast natural gas deposits, the United States has become the world leader in natural gas production.

Energy production in the United States has shifted throughout history, but the legacy of Hart's business has survived with the renovated natural gas industry. Through recent discoveries, natural gas has become a main source of energy, especially in the United States. Hart's contributions to the energy industry were important both for his supply to a newly industrialized economy and through the creation of a new facet of American energy production. However, while natural gas might be a very profitable alternative to oil and coal, it is still a nonrenewable energy source. Fracking and natural gas might have helped ease financial problems with energy, but it is still a fossil fuel.

Gold-Mining Technologies

Gold mining is the process of locating and extracting a pieces or shards of gold from the earth, typically via caves, deep pits, or mines. Since gold's discovery, many miners or searchers have used the technology of iron tools and makeshift wooden strainers to retrieve it.

There are three main factors that affect gold mining. These include exploration, mining, and placing. Exploration is the search for a possible location of gold. Mining is the bulk of the work, in which miners extract the gold from the ground. Last, nuggets of gold undergo a process called “placing” that separates them from the earth built up around the metal.

Evidence of gold mining can be found from as long ago as 4000 BC. Gold artifacts from the Bronze Age (3300–1200 BC) abound both in Europe and the Middle East. Bronze Age North American indigenous cultures also mined gold, particularly in areas of modern-day western Mexico and Colombia. Andean and Argentinian cultures also mined the metal.

The earliest gold mining in the United States took place in 1799 in North Carolina. While the western states are the most famous for gold mining, states as unlikely as Alabama and Florida have produced small amounts of gold. Large-scale gold mining did not begin in the United States until the discoveries in California in 1848. Known as the California Gold Rush, over 300,000 people migrated to California (which was not yet a state) in hopes of profit. A plethora of miners from all over the country and the world encouraged other economies as well, from agriculture to international trade. Boomtowns—some permanent, like Sacramento and San Francisco, and others impermanent—significantly expanded California's population.

While the Gold Rush made California an important state, it also had many negative effects. Mining causes significant environmental degradation. The Gold Rush also initiated the California Genocide wherein over 100,000 indigenous people died in the 20 years after 1848.

Gold-mining technology in the early 1800s consisted of general tools: shovels, picks, and pans used to extract the metal. The shovel was for digging deep in caves or in the ground; picks separated the embedded metal from the earth, and pans or bowls helped separate other particles from the gold. Water, or any other convenient liquid, was placed into the pans or bowls with the gold, helping separate it from any dirt.

Cradles were used when large amounts of gold were discovered. They resembled child's cradles but had screens at the bottom. Miners deposited large amounts of gravel, dirt, and sand in them and added water. Using a rocking movement, even the smallest pieces of gold could be recovered. This was the most effective and efficient tool for separating gold from anything attached to it.

Placer mining provided a bonanza of gold from riverbeds. Groups of prospectors or mining companies diverted water from them, exposing the river bottoms. This type of mining required considerable investment in equipment and time.

Some countries used other methods that did not include water. Arrastre was a form of dragging used to obtain gold. Powered mainly by horses and mules but sometimes water, a mill would drag large pieces of gold ore against stones to extract the metal.

By far the most environmentally destructive method of gold mining is hydraulic mining. Developed in 1853, hydraulic mining uses a high-pressure water hose to break down gold-bearing areas from hillsides to river beds. Loosened rock, gravel, and dirt are run through large sluices that function like elongated cradles. Gold collects at the bottom of the sluice while dirt and rock washes out. As for gold in rivers or canals, a hydraulic system was created to pump it out as miners scooped up gold and gravel and eventually placer the findings.

Gold was also mined in traditional, deep-earth mines. For example, the Elkhorn Mine in Montana often excavated gold, silver, and copper from the same mountain. Men from Wales and Ireland specialized in this type of mining, which was dangerous, low-wage work.

Chinese Americans worked in mines, often in auxiliary services like food production and

laundering, but also as gold miners of a sort. Areas with particularly rich gold sources would create rock waste, or tailings, that Chinese immigrants and others would remine. Anti-Chinese racism ran as high as anti-Native American racism in the American West.

Currently, gold-mining technology is far beyond the methods of simple iron tools. Such devices like metal detectors and drills have significantly advanced the search for gold. Gold remains one of the world's most sought-after metals as it is extremely valuable. Some mining methods, such as arrastre and the hydraulic method, are still used today. However, they have advanced—horses and mules no longer carry the burden of pushing the mill, because large machines now take care of this. As for hydraulic mining, the pressure in water is increased by applying jets to the pump.

The best place to discover gold today is South Africa.

Goodyear, Charles (1800–1860)

Charles Goodyear was born December 29, 1800, in New Haven, Connecticut. He is best known for discovering the process of vulcanizing rubber.

There was a “rubber fever” in the early 1830s, but it ended when no one seemed to be able to cure the problems of rubber freezing into a hard substance in the winter and melting into a smelly, gooey substance in the summer. Rubber factories went bankrupt in less than five years of opening.

Goodyear himself had been bankrupt when he first became seriously interested in rubber. He began working with natural rubber in 1834, when he was in a

Philadelphia debtor's prison. His wife brought him a batch of raw rubber, and he began experimenting relentlessly on it. He tried various products to absorb its stickiness. Nothing seemed to work well.

Goodyear moved his family to New York City, where he set up a laboratory in a friend's fourth-floor tenement bedroom. His brother-in-law lectured him about the sufferings he was putting his wife and children through, but Goodyear persisted in seeking a way to make rubber usable and profitable.

He made progress and even won a trade show prize for his work. However, his breakthrough came as the result of an accident—he applied nitric acid to remove bronze paint from a rubber sample, which turned black, and he tossed it in the garbage. But he remembered that the sample felt different from any others, so he retrieved it and noticed that it was smooth and dry.

This accidental success was enough for him to get backing from a New York businessman. The timing was not good. An economic depression wiped out the business, and Goodyear and his family, in poverty once more, moved into the abandoned factory, living on the fish he could catch. Eventually, Goodyear found other backers and manufactured 150 mailbags for the U.S. government. But the bags were left in a hot room and melted.

A happy accident again came to his rescue after five years of experiments and living off the charity of Massachusetts farmers in Woburn. In 1839, Goodyear was using a gum-and-sulfur formula. Angered by mockery from people in a store, Goodyear lost control of his rubber, and it flew onto a very hot potbellied stove—and it became weatherproof. More work had to be done to perfect his result. He needed to know how much heat to apply and for how long to the right amount of rubber.

After suffering many crises, including the loss of an infant child, Goodyear finally found the right combination of processes to vulcanize rubber. He also found a backer: his brother-in-law. Unfortunately, Goodyear divested himself of his manufacturing interests and went back to experimenting with rubber. He viewed it as a type of elastic, and indeed, many modern uses of rubber were first posited by him: rubber paint, rubber plastic for food packaging, car springs, ferryboat bumpers, and so on.

Although Goodyear had discovered how to vulcanize rubber, in England, Thomas Hancock patented such a process just before Goodyear did. Goodyear had salvaged his American patents thanks to the aid of Daniel Webster, but he was involved in a seemingly endless series of litigations in Europe. Unfortunately, Goodyear was not a good businessman and continued to lose money while others profited from his work. When he died in 1860, he was \$200,000 in debt—an enormous sum for that time. However, his patents eventually enabled his family to live in comfort. In 1898, after his death, the company was named after him.

Grain Elevator

Grain elevators served to keep crops safe and preserved while in transport beginning with their invention in 1842 by Joseph Dart. Grain crops are an essential ingredient in many of the foods we eat today, but it would not be until the 1800s that grains became mass-produced. Most American grain production has involved the Midwest region of the United States. Some other areas could only use such crops if they were transported to them, which was a rather difficult task at the time.

The transportation of grain to the East would become easier with the construction of the Erie Canal, established in the year 1825. The canal proved successful and raised the status and importance of the city of Buffalo, but it raised another issue. The amount of grain being shipped, along with the size of the ships used to do it, prevented further travel on certain waterways. Grain had to be unloaded and then reloaded onto smaller boats that would fit on the canal. This process took as long as a few days to as much as a week. Joseph Dart noted this dilemma and thus created what is now known as the grain elevator.

Grain elevators dominate a freight yard in New York City, ca. 1890. Such elevators played a crucial role in the transport of grains during the early years of expanding railway systems. (Three Lions/Getty Images)

Born in 1799, Dart had made his way to Buffalo at 21 years of age to pursue a partnership with merchant Joseph Stockholm. Their short-lived partnership led Dart to the grain trade. The canal carried heavy traffic, and when not all of a ship's grain could be loaded onto a smaller boat, it still all had to be unloaded from the larger one. Again, such a process would take a whole crew of stevedores days or even weeks to complete. It could take much longer if the weather was inclement. Dart observed that the process cost travelers time.

To address the problem, Dart hired Robert Dunbar, an engineer with prior experience with mill projects, who helped him create the grain elevator in 1842. The elevator took inspiration from the steam-powered flour mills that Oliver Evans had invented many years before. For example, Dart borrowed the idea of the conveyor belt for his own mechanism. It would also be steam powered—and constructed out of wood due to the supply available in the city of Buffalo.

The stevedores, however, who were mostly Irish immigrants, did not favor the invention, as it was intended to do their job faster and more efficiently, eventually leaving them out of work. Many doubted the elevator would even function. But Dart's grain elevator accomplished what it set out to do and more: it significantly cut the time needed to unload ships and acted as storage for whatever grain was left behind to be picked up later by local merchants. What used to take a week now took a mere few hours. The *Philadelphia* was the first ship to be unloaded mechanically with the use of Dart's elevator. The grain was directly taken from the ship and lifted into the storage bins on-site. It did not take much longer for Buffalo to see another elevator built, and it started a chain of more elevators. By 1848, at least six elevators operated along the Buffalo River, quickly rising to a count of 20 by 1860.

Gridiron for Cooking

A gridiron is a frame of parallel bars or beams that are typically in two sets arranged at right angles, to be used as a cooking grill. It is used over an open flame and can be used to cook a variety of foods. Many gridirons were made and patented in the United States in the 1800s, and over time, many have been developed specifically for different types of food. A combination hinged gridiron was developed and patented by Amasa and George Sizer in 1836. The steel wire gridiron was patented by William C. Perkins in 1889; it would hold meat in place for broiling.

Today, gridirons are used to broil food especially in fast-food restaurants. Gridirons come in different shapes and sizes depending on the use. Usually, they are a square or rectangular, but they also can be circular or oval. Gridirons are usually made with iron or cast iron, but any other metal that is suitable for cooking may also be used.

Hand-Cranked Ice Cream Maker

Ice cream is a dessert that one consumes to satisfy a sweet tooth as well as a way to treat oneself in hot weather. Today, there are many flavors and sizes to

choose from—options that were uncommon many years ago. And ice cream is now considered one of the most common and affordable sweet treats, unlike in the past, when it was associated with the wealthy and those of higher status because of its labor-intensive and time-consuming preparation. Nancy M. Johnson invented the mechanism that made it easier for more people to have ice cream.

Ice cream was not introduced to America until the mid-1700s by Governor Blandon of Maryland. In that era, its ingredients were either not readily available or rather expensive. Ice, for example, was only available to those who had access to frozen lakes and ponds, and once collected, it had to be stored in insulated chambers.

The most common process used to make ice cream leading up to the mid-1800s, the “pot freezer” method, called for two pots of different sizes, each filled with different ingredients. The larger was filled with ice and salt and the smaller with cream, sugar, and a flavoring. The mixture had to be stirred frequently to prevent the formation of large crystals, which caused a dense consistency. Such a process could take up to an hour before the ice cream was ready. Johnson came up with a solution that cut down the time and made things much easier for those who wanted to make ice cream themselves.

Johnson received a patent on September 9, 1843, for her hand-cranked ice cream machine. Her mechanism applied the same idea of the “pot freezer” method but with an improved approach. Her machine used a wooden bucket for the ice and salt, and it also held a metal container filled with the ice cream mixture. The metal container was covered with a lid that had a built-in paddle connected to the crank, and the moving parts worked simultaneously. The paddle made all the difference. As the crank operated, it scraped layers of material from the inside of the tin container, preventing larger crystals from forming within the mixture and allowing a much smoother consistency. With Johnson’s invention, the time to make the dessert was cut to half an hour.

Despite it being a 170-year-old method, ice cream is still made today using Johnson’s innovation.

Health Reform

During the antebellum period, health reform developed as a challenge to traditional medical practices. Until the 19th century, the study of medicine had been based on the belief that the body was made up of vital forces or humors. Mostly male doctors sought to remedy this imbalance with bloodletting, enemas, lancing boils, or by inducing vomiting. Following the reform impulse of the Second Great Awakening (1790–1840), however, social reformers, many of them women, promoted alternative means to achieving health, including vegetarianism, exercise, and daily bathing. This widespread movement for health reform took the responsibility of good health out of the hands of doctors and placed it in the hands of ordinary men and women.

Beginning in the presidency of Andrew Jackson (1829–1837), the United States experienced a period of urbanization and industrialization. Evangelicals argued that society was suffering from moral downfall as the result of economic development and the expansion of cities. Consequently, reform movements directed at perfecting society were established, including antislavery, women’s rights, temperance, education, dress reform, and health reform.

Until approximately 1830, medical practices in the United States had been based on the ancient concept that health depended on the alignment of vital forces or humors. When one of these humors became imbalanced in the body, a person became ill. Medical

doctors believed that excess fluid must be released to restore the humors. Doctors' practice of bleeding patients for tuberculosis or women recovering from childbirth killed uncounted women, though the medical profession had difficulty realizing that its practices harmed more patients than it helped.

The health reform movement first gained support in New England, where sectarian medicine replaced some orthodox medicine. Sectarian medicine differed from traditional medicine by promoting daily bathing, limited diet, and moderation in sex, exercise, athletics, and fresh air rather than violent purging or bloodletting. These practices were especially appealing to women, because they fell under the realm of the home and its management.

According to antebellum practices, women's proper place was within the private sphere of the home, and their roles revolved around domesticity. Women were also thought to be naturally more moral than men and therefore closer to God, a belief emphasized during the Second Great Awakening. This meant that it was a woman's responsibility not only to uphold the home but to maintain the health and morality of the family through personal action and child rearing. Health reform specifically appealed to women because it placed the responsibility of health in the hands of the individual and promised to target illness and sin. Health reform promoted noninvasive cures for physical maladies from which women suffered, including physical weakness, menstrual distress, and nervous disorders. Industrialization also contributed to women's interest in health reform because, with more factory-produced goods available, the need for home production decreased. As a result, women found themselves with free time to dedicate to the preservation of their homes and specifically to their own health and the health of their families.

Among the most famous health reform leaders was Sylvester Graham (1794–1851). Graham, along with his fellow advocate for vegetarianism William Andrus Alcott (1798–1859), argued that illness could be cured with diet and exercise. He promoted vegetarianism and invented the Graham cracker, which he argued was healthier than purchased bread that had chemical additives. Graham had begun as a temperance reformer, which led him to conclude that gluttony

in food as well as drink was unhealthy. In 1830, Graham also began lecturing on the merits of daily baths. Graham disciples Mary Grove Nichols (1810–1884) and Paulina Wright Davis (1813–1876) also advocated for vegetarianism and improved hygiene. Nichols and Davis joined the lecture circuit and traveled around the country speaking about the benefits of health reform.

Hydropathy is perhaps one of the most well-known divisions of health reform. Popularly known as the “water cure,” hydropathy appealed to both men and women and promoted the consumption and use of water to cure illness. In addition to drinking and bathing in fresh water, hydropaths encouraged douches, wrapping patients in wet sheets, and submerging them in water. Combined with fresh air, exercise, healthy diet, and limited sex, hydropathy promised to cure any ailment. Hydropathic practices could be applied at home, which made it accessible to all classes, but spas where room and board could be obtained for a fee were popular with the upper and middle classes. Hydropathy specifically targeted female patients because it proposed to cure complaints related to nervous conditions, menstruation, and childbirth. Health reformers also targeted women's fashion as one cause of illness, because they claimed that corsets constricted organs and that long skirts spread disease by catching trash as women walked through the streets.

For women, hydropathy also offered opportunities to practice medicine that were unavailable elsewhere. In 1851, Mary Grove Nichols and her husband, Thomas Low Nichols, opened the American Hydropathic Institute. Hydropathic doctor Joel Shew (1816–1855) and his wife, Mary Louise Shew, promoted the water cure as part of midwifery. Harriet N. Austin (1825–1891) worked as a water cure physician, writer, and health reformer, and Rachel Gleason (1820–1905), along with her husband, Silas Gleason (1818–1899), made women's health their water cure specialty.

Health reformers also influenced other groups to adopt health reform. During the 1860s, Seventh Day Adventists, under the guidance of Ellen White (1827–1915), adopted vegetarianism and diets with simple foods. John Harvey Kellogg (1852–1943), creator of the cornflake, was a holistic doctor who promoted vegetarianism, exercise, and enemas.

Henry, Joseph (1797–1878)

Joseph Henry was a 19th-century American scientist who made important discoveries in magnetism and electricity. His scientific work and his skill as a promoter of science were recognized when he was chosen as the first secretary of the Smithsonian Institution.

Born in Albany, New York, in 1797, Henry moved to the small town of Galway, New York, as a child following his father's death. There, he began to study science and won a scholarship to the Albany Academy, a prestigious preparatory school. His academic performance won him a teaching position at the school in 1828. He took several years to finish his studies because the growth of his family prompted him to take work as a surveyor.

While teaching at the Albany Academy, Henry began conducting experiments on electromagnetism. He made a number of important discoveries, including a method of strengthening electromagnets to allow the transmission of current over long distances. This discovery underpinned all later research on electric motors and power transmission. To demonstrate his discoveries, Henry unveiled a prototype telegraph. Not realizing the commercial potential of his work, Henry failed to patent it—and after early encouragement, he broke off a burgeoning friendship with Samuel Morse

when Morse tried to patent and commercialize his own telegraph. The scientific value of Henry's work became truly apparent only years later; the property of inductance he revealed showed that changing the current through a material conducting electricity created a magnetic field. Independently discovered by the British physicist Michael Faraday, this principle is at the heart of all modern research in electronics.

As a result of Henry's work and his reputation as an excellent teacher, he was hired in 1832 as a professor of natural philosophy at the College of New Jersey, now Princeton University. He continued to publish on electromagnetism and other subjects (including astronomy, optics, and acoustics), building an increasingly strong reputation. In 1837, he toured Europe and established relationships with a number of prestigious scientists there.

In 1840, Henry was elected to help manage a collection of artifacts returned to Washington, D.C., by the U.S. Exploring Expedition of 1838–1842. Concerns over the preservation of this collection helped spark interest in establishing a national museum. This led to the establishment of the Smithsonian Institution. In 1846, the board of regents for the new Smithsonian Institution offered Henry the role of secretary, close in practice to the modern title of chief executive officer. He made the difficult decision to leave Princeton and uproot his family, arriving in Washington, D.C., in 1847. While Henry detested the climate of Washington and was absent most summers, he threw himself quickly into his work. Shortly after arriving, he focused the Smithsonian on the support of scientific research in a number of fields. He donated the Smithsonian's book collection to the Library of Congress and launched a scientific journal in 1848.

Henry worked tirelessly to establish a true scientific community in the United States. He provided grants to promising researchers, encouraged a network of volunteers to provide meteorological data, and established an international exchange to distribute scientific papers across the world. His meteorology network became the basis of scientific weather forecasting. In 1852, he was appointed to the U.S. Light-House Board. As a board member and later chairman, Henry had influence over a large research budget—16 times that available to the Smithsonian.

During the Civil War, Henry advised the military on aerial observation (the use of hot air balloons in military espionage and battlefield strategy planning) and other new technologies. In 1863, he helped found the National Academy of the Sciences, an organization that is still powerful today. He continued as the secretary of the Smithsonian, as a board member for the National Academy of the Sciences, and as an active board member and researcher for the National Light-House Board for years. He suffered a stroke in December 1877 and died in April 1878. One of his last acts was to advise and encourage Alexander Graham Bell as he developed the first prototype telephone.

Hoop Skirt

A hoop skirt is a garment worn under a woman's skirt or dress that is designed to flare it out. Once the hoop apparatus is fashioned around the wearer's waist, the clothing is placed over the hoops, encircling the wearer in fabric and creating some type of bell shape, depending on the era, to the woman's silhouette. The desired effect is to create aesthetic appeal to the opposite sex with full hips and slender waist. Variations of this fashion garment have been worn for almost three centuries. Desire for the popular undergarment fueled booming technological advancements in shipping and later the steel industry, spanning multiple continents.

During the European Renaissance era (12th to 15th centuries), the Spanish, French, and later the English manufactured this undergarment, then referred to as a farthingale. Made from whalebone bent into circles of graduating sizes that were sewn onto linen fabric that was belted around the waist, the hoops would be placed over petticoats or crinoline undergarments and then cinched at the waist of the wearer,

accentuating the figure. As noted, this was to create the illusion of a slender waist by augmenting the hips.

Variations of this garment continued to appear throughout Europe and America. Examples included "panniers," which were hoops worn exclusively over the hips, during the 1680s–1750s. These kept the front and back of a dress flattened to the wearer's body, flaring out only its sides. The hoop petticoat, cage crinoline, or cage petticoat had hoops made from wire, whalebone, or cane sewn into a petticoat (steel was used after 1857) that widely encircled the wearer during the 1860s.

The labor-intensive making of these garments, plus the cost of materials and the fact that they restricted movement, meant that only very wealthy women used them. With the advent of the Industrial Revolution, or "crinoline period" in America—and the invention of the sewing machine—factory production of hoops increased; the cost therefore decreased, so the product could reach a greater audience of women of all social classes who, like their more affluent sisters, could now avail themselves of the latest in fashion.

As demand grew greater, industries sprang up to keep up with the cyclical fashion industry. Europe in the 1700s witnessed an increase in whaling and, as an offshoot, in shipbuilding to keep up with orders that included bustles and crinolines. Later on, steel manufacturing increased to meet the increased demand for new fashion devices. Ultimately, this drove costs down.

Fashion styles came from Europe and France, emulating those of the upper classes and royalty during the colonial period and on up to the 20th century. American women copied European fashions infused with their own aesthetic; skirts and dresses were heavily draped in layers of rich fabric and flared out (as much as 15 feet in diameter) with the aid of hoops. Hoop skirts achieved the most prominence during the antebellum period in 19th-century America, typically in the Southern states. The modern predecessor of the hoop skirt was inspired by the architectural style of the Crystal Palace in England from 1851. Patents were issued (often for women) for variations and improvements on hoop designs, so popular was the undergarment.

The first wave of American feminists found 19th-century women's excessive clothing confining, inhibiting even simple movements. Surviving letters from women migrating to the American frontier wrote that some women chose to wear their hoops despite their

impracticality amid the rigors of overland travel. Whether by covered wagon or travel by train, the cumbersome nature of the hoop skirt did not lend itself to any practical uses and, indeed, it only added to an already difficult journey. Letters record people witnessing Native Americans wearing European style clothing.

During the American Civil War (1861–1865), hoop skirts realized a practical and rather creative function, joining the war effort as vehicles for smuggling contraband to husbands, fathers, and brothers into enemy territory. Records from the era record that the skirts could conceal food, ammunition, and clothing and even enterprising men wishing to end their participation in the war, carefully hidden in the folds of material enveloping the hoop skirt. By the end of the Civil War, hoop skirts were discarded in favor of simpler dress styles, reflecting a changing society.

Horse-Drawn Streetcar

Also known as a horse car or horse-drawn tram, horse-drawn streetcars were designed and patented in the 1830s by John Stephenson, who also designed and created the New York and Harlem railway in November 1832. John Stephenson is credited with creating the first modern tramway.

Stephenson was born in 1809 in Ireland and migrated to the United States with his family when he was two years old. He attended public school in New York City and finished his education at Wesleyan University in Connecticut. In May of 1831, he created his own business, known as John Stephenson Company, and was greeted by a series of both breakthroughs and misfortunes. Originally, Stephenson designed omnibuses: large, horse-drawn carriage buses. In the early 1830s

John Mason, a powerful merchant and banker, paid Stephenson to develop a horse car for the newly created New York and Harlem railway, an early urban streetcar system. Stephenson developed the first streetcars for Mason's company and patented his design in 1833.

Stephenson suffered a bankruptcy in 1842 when his business finally collapsed after years of financial issues created by "the panic of 1837," when bonds he had accepted had become virtually worthless. However, his spirit could not be broken. Each time he experienced a setback, he picked himself up and moved on. In 1843, he reopened his business and was met with incredible success. For years, his company was the dominant manufacturer of streetcars. It is estimated that his firm created 25,000 of them between 1876 and 1891 alone. When he passed in 1893, his factory was producing 25 cars a week and had hired 500 employees to meet that goal. The story of John Stephenson is a tale that represents human willpower and the ability to persevere. Even though there were countless deterrents in his life, Stephenson refused to yield. It is because of this action that John Stephenson was able to completely change how public transport operated and how society views public transport.

Horse-drawn streetcars are similar to modern trolleys except that they are moved by actual horsepower rather than electricity. This mode of transportation was more efficient and essentially the precursor to buses and bus routes, as they followed a set path and arrived at each destination within an allotted amount of time. The grooves in the railway that trams were attached to allowed the horses to pull a heavier load much more easily, and the riding experience was less turbulent.

Initially, horse-drawn streetcars were pulled by four horses each and were capable of carrying up to 30 passengers in their compartments. By cutting the weight of the streetcars in half—from 6,800 to 3,500 pounds—Stephenson's cars could use two horses to pull rather than four. This meant that more streetcars could run at once. Fewer horses also meant less horse manure—which caused immense public health problems. Stephenson accomplished the drastic decrease in weight by building the carriages with woods like hickory instead of oak. He also modified the structure, removing doors and simplifying passenger accommodations. Stephenson continuously sought to improve upon his

initial design and was documented as filing at least 11 patents in the process.

Hospital Transport Service, Women's Department

Established in the early days of the American Civil War by Frederick Law Olmsted, the purpose of the Hospital Transport Service (HTS) of the U.S. Sanitary Commission was to charter, supply, and maintain a fleet of riverboats to use as floating ambulances as

well as floating hospitals. The HTS served the Union Army and employed countless numbers of female nurses in its Women's Department.

The U.S. Sanitary Commission itself, a civilian organization, was created on June 9, 1861, and was given the authority, in cooperation with the Union medical department, to establish medical guidelines in the field, inspect medical facilities of the military, and provide medical supplies as needed. To this end, the HTS pressed or leased into service a fleet of ships of various shapes and sizes, including paddleboats and steamboats. The HTS operated in both the Eastern and the Western Theaters of the war, particularly on the Virginia and Mississippi Rivers. In many cases, wounded and sick soldiers were transported to the hospital ships to either be tended to where medical facilities lacked on the shore or to evacuate and triage soldiers who then were brought farther north, behind Union lines. In the Eastern Theater, many of the hospital ships transported soldiers to large cities for further treatment and convalescence, including such northern locations as Washington, Philadelphia, and New York. The HTS employed a variety of ships for use in the Union medical system, including the *City of Memphis*, the *Daniel Webster*, the *Red Rover*, the *Wilson Small*, the *Knickerbocker*, and the *Elm City*. By the end of its service, the HTS employed more than a dozen hospital ships serving in the various theaters of the war.

At the start of the war, civilians and political leaders in the Union, and much more prominently in the Confederacy, heatedly debated the role of women not only in the medical services but also in the military. Women faced opposition by both civilian and military organizations based on the view that war and medicine were not proper spheres of activity for respectable ladies. Also, many Americans believed that the constant close proximity of women to male bodies, bodily fluids, and disease would compromise female honor and virtue. But as the war continued to rage over the years, attitudes toward the presence of women in the medical services shifted as women proved themselves. During and after the war, society came to view nursing as an extension of a woman's "natural" role as caregiver. Thus, the HTS and the U.S. Sanitary Commission played important and active parts in redefining

gender roles in warfare and Northern society during the 19th century.

During the opening days of the Civil War, many of the white, upper- and middle-class female volunteers accompanied their husbands or other family members into military service in the hopes that they might both serve their country and stay close to their loved ones. These women rarely possessed any formal medical education and were, in many cases, viewed as nuisances by the Union Army. Along with these women, both Catholic nuns and escaped female slaves volunteered to aid the military in its fledgling medical system. Harriet Tubman, for example, did some nursing during the war, though she primarily served as a spy and scout for the Union Army.

In the beginning, the primary role for white, female volunteers was to supervise the freed slave men and women and the convalescent soldiers who worked as servants and orderlies on the hospital ships. However, as the war progressed and the number of sick and wounded soldiers began to overwhelm the Union medical staff, these volunteers began taking a more active role in the medical care of wounded soldiers.

These women became more involved in the daily planning and provision of necessary medical care for the soldiers on board the hospital ships. Many of their daily tasks included assisting the army medical staff with operations and treatment, supplying patients with medicine, tending to the nutritional needs of the soldiers, and cleaning and restocking the ships for new patients during the return trips to the front. According to Civil War statistics, approximately 3,200 Northern women, mostly white, middle-class volunteers, served in the Hospital Transport Services and the United States Sanitary Commission during the course of the American Civil War, when the hospital ships carried approximately 10,000 wounded or sick soldiers from the battlefield to safety behind the lines.

The Hospital Transport Services' influence began to decline by late 1862 and early 1863, particularly as the wartime action moved farther away from the major rivers and toward the interior of the Confederacy. Along with the relocation of the battlefronts during the war, the Services also began to decline due to the appointment of Jonathan Letterman to the position of medical director of the Army of the Potomac. In his

post, Letterman reorganized the Union medical system to create a highly effective ambulance service, making the civilian-run Hospital Transport Services obsolete—though not the hospital ships. By the summer of 1862, Olmsted recommended to Letterman that all of the medical transportation services, both military and civilian, be consolidated under the Medical Bureau and the hospital ships be transferred to the jurisdiction of the quartermaster department. The United States Sanitary Commission continued to support the Union Army in the war effort until it was disbanded in July 1865.

Howe, Elias (1819–1867)

Elias Howe Jr. of Spencer, Massachusetts, invented the sewing machine. Howe belonged to a poor family and struggled to overcome poverty while working to create his invention. Passionate about machinery and inventing, Howe sought to relieve women and children of the burdens of hand sewing. He had watched his family struggle to mill cotton and had desired as a young child to free them of this laborious job. Before the creation of the sewing machine, women and children worked in textile mills, sewing clothing, shoes, and other materials together by hand. Conditions inside the mills were dangerous and burdensome. Although society initially rejected the sewing machine, Howe's invention changed the course of labor for women forever.

Born in 1819, in Spencer, Massachusetts, Elias Howe Jr. was the son of a cotton farmer and miller.

Elias Howe invented an efficient sewing machine in 1845, which revolutionized the country's industrial sector and changed life for countless homemakers. It was the first product of the Industrial Revolution targeted at the female consumer. (Metropolitan Museum of Art)

Like most farming families, the Howe family was large, with eight children. From a young age, Elias Howe had worked alongside his brothers and sisters on the farm to clean cotton and prep it for sale in a process called “carding.” With a desire to be independent and help his family, Howe eventually left home to work at a machine shop in Cambridge, Massachusetts. Howe was a quick learner, mastering the machinery with ease—such as spinning machines and power looms—due to his apprenticeship experience at Lowell cotton mills.

In 1841, Elias Howe moved to Boston after marrying Elizabeth Jennings Ames. The couple had three children: Jane Robinson Howe, Simon Ames Howe, and Julia Marie Howe. Originally, Howe struggled to create his invention because he lacked funding to purchase or make parts. But an English investor helped him to complete the sewing machine in May 1844. Howe patented it 1845 and immediately began improving his

design when he realized that others had stolen his idea. In 1854, after establishing his rights to the machine, Howe's fortune grew as manufacturers started purchasing it. The needles on his machines had the eye at the point, an automatic feed, and a lockstitch function.

Elias Howe died at age 48 in 1867. Although he only enjoyed success for a short time, Howe remains an influential mechanical engineer whose project enabled the mass production of clothing and brought progress to the textile industry. Howe's design for the sewing machine laid the foundation for all modern sewing machines.

Howe Truss

Patented by William Howe in 1840, the Howe truss was an innovation in civil engineering and public transportation. The Howe truss bridge belongs to the family of truss bridges because it employs a structure formed by constructing triangular shapes that enable the bridge to support heavy weight. The Howe truss design incorporates horizontal pieces that enclose diagonally and vertically placed pieces in the middle. Built of wood and iron, the bridge became popular because of its durability and strength.

William Howe, a farmer in the rural town of Spencer, Massachusetts, was the descendant of the inventor Elias Howe. The Boston and Albany Railroad company contracted Howe to build a railroad bridge over the Connecticut River in Springfield, Massachusetts, because he was a talented inventor and bridge engineer. Howe developed the Howe truss bridge after studying truss bridge structure and improving the quality of other truss bridges.

The Howe truss consists of vertical iron pieces attached to wooden diagonal pieces. Typically, the wooden parts were of white oak, cedar, pine, fir, or hemlock. The iron pieces made the truss bridge stronger and more durable, able to support heavy trains. Wood and iron together enable the bridge to resist tension. The diagonal support beams slope upward and toward the middle, which redirects compression to the top of the bridge. The bridge components endure force individually so that each member can safely support its proportion of weight.

By using iron, the Howe truss bridge could extend across greater distances, such as canyons and riverbeds. Iron also eliminated some of the weight of traditional wooden panels. For this reason, Howe's design became popular among 19th- and early 20th-century engineers because of its simplicity: it made construction easier and faster. Once the Howe truss became popular in the United States, other countries, such as Russia and Germany, began to use the design.

The Howe truss improved public transportation and the transportation of goods because it improved the safety of train travel. The design of the Howe truss also enabled goods to travel farther.

Interchangeable Gun Parts

Firearms manufactured before 1700 were made by hand. Each gun was one of a kind and expensive. If a part broke, the gun was sent to a gunsmith to determine if it could be repaired with a new handmade part

or if it was impossible to fix. What if a broken part could be taken out and replaced with a new, identical part? The gun would be usable again. This was the purpose of interchangeable gun parts.

Simeon North (1765–1852) owned a farm and a mill in Connecticut. North's mill manufactured metal scythes. North also took orders to make pistols. Both products were known for quality and durability.

The U.S. government contracted with North in 1799 to manufacture 500 pistols, when guns were produced one at a time. Craftsmen made all the parts for each gun and then assembled it. North and others worked to develop guns with interchangeable parts. He chose a different assembly method to fulfill a government contract in 1808: he had one worker make numerous copies of only one part of a gun while another worker made copies of another part, and so on, until all the gun's parts had been produced in quantity. Then a gunsmith took one of each part and assembled a gun. Using this method, more guns were produced in less time.

Handmade parts were not completely interchangeable, so any irregularly shaped parts had to be milled or shaved to exact sizes to fit together properly. If gun parts didn't fit precisely, the gun wouldn't work. North's 1813 government contract stated that the guns he manufactured would consist of parts that could be exchanged with any other gun produced at the same time. Only a machine could produce multiple copies of a part of uniform size and shape. Many credit North as the inventor of the first milling machine—which cuts metal in a pattern or shape to exact specifications.

North's milling machine produced parts that were the closest to achieving interchangeability at the time; yet they were not 100 percent interchangeable. Parts' dimensions were checked with gauges for accuracy, and workers still had to file some of them to complete a gun assembly. Machine tools were needed for precision cuts to achieve interchangeable parts, and jigs were developed to guide the exact dimensions of the machine cut. Devices were developed to hold a sheet of metal being cut without movement so that a precision cut could be achieved.

U.S. armories as well as private arms makers worked to produce interchangeable parts. The military saw the value of these parts because with them, guns broken on the battlefield could be repaired on the spot. The U.S.

armories in question were in Springfield, Massachusetts (established 1794), and Harper's Ferry, Virginia (founded 1798). Armories maintain and store firearms and ammunition, and some also manufacture firearms.

Thomas Blanchard (1788–1864) was an outside contractor for the Springfield Armory to make wooden rifle stocks. Blanchard became an inside contractor in 1822, which gave him the use of the armory's shop, tools, water power, and raw materials. Within four years, rifle stocks were being produced by a series of machines that Blanchard invented.

John H. Hall (1781–1841) patented the breech-loading rifle in 1811. Hall oversaw its manufacture at the Harper's Ferry Armory Rifle Works. The M1819 rifle's advantages over a muzzle-load rifle were its speed of load and reload, reliability, endurance, and its interchangeable parts. Hall invented several special-use machines to cut the wood and metal pieces of a gun to precise specifications as well as a system of gauges (work, inspection, and master) to measure accurately the size and shape of the machine-made parts.

Private arms makers and government armories achieved interchangeable gun parts by use of machine and gunsmith precision filing by 1828. It would be over 70 years before 20th-century technological advances improved machine precision to be greater than a skilled 19th-century gunsmith's precision with a file and gauges.

Inverted Microscope

The inverted microscope has its light source above the scope stage, while the objects to be viewed are placed below the stage, pointing up. The inverted microscope was invented by John Lawrence Smith in 1850.

Smith (1818–1883) was a professor of chemistry at the University of Louisiana (now Tulane University) when he invented the inverted microscope. His broad research interests included agricultural chemistry, geology, and mineralogy. He first described his invention to the Société de Biologie in Paris in 1850 and then to the American Scientific Association in 1851. The microscope was originally manufactured by Nachet in Paris, but since the company did not mention the inventor's name, Smith gave a full description of his invention in the *American Journal of Science and Arts* in September 1852.

The inverted microscope was designed to overcome the shortcomings of other microscopes used at that time in chemical and geological research. According to Smith, traditional microscopes constrained the user's ability to manipulate objects because of the limited space between the object and the stage. Moreover, condensation and vapor from objects would obscure the view. Finally, it was impossible to heat the objects under view without damaging the microscope. He solved these problems by placing the object beneath the stage and the microscope optics above it.

The inverted microscope allows users to handle large samples as well as those that must be kept under particular conditions (for example, in a thermostatic chamber). Unlike other microscopes, the inverted microscope situates the objective below the specimen, and light comes from above via a condenser before being diverted via a prism. In Smith's design, the prism has angles of 55°, 52.5°, 107.5°, and 145°. The light from the source goes through the specimen and then, via prism, is directed to the output eyeglass, which is mounted on a tube inclined at an angle of 35°. Focus is achieved by a clever system of three tubes that slide onto each other—one is fastened to a plate attached to the prism, while the middle one keeps the projecting collar and rests on two springs. The up-and-down movement of the focus assembly is achieved by moving a screw. This design allows the prism to remain accessible and to be wiped off before observation.

In addition to the ability to accommodate large samples and those that need a special environment, the inverted microscope allows the use of different illumination for observing structures in reflected light.

Modern inverted microscopes are commonly used to study chemical reactions and in metallurgy, and those used in microphotography and cinemicrography are designed to hold cameras.

Jervis, John B. (1795–1885)

John Bloomfield Jervis was an American civil engineer known for his design and supervision of the construction of five of America's earliest railroads. He was also the chief engineer of three canal projects and built the 41-mile Croton Aqueduct, which was New York City's fresh water supply line from 1842 to 1891. He designed the first American locomotive truck, the Sturbridge Lion.

John Jervis was born in Huntington, New York, on December 14, 1795, and would be the oldest of the seven children of Timothy Jervis. With his family, he moved to Rome, New York, where his father ran a lumber business. John was an axe man who cut down bushes and trees along the Erie Canal, eventually working as a resident engineer in charge of a section 17 miles long. He was promoted to general superintendent of the Eastern Division of the Erie Canal in 1824. He left that job and became a chief engineer of Delaware and Hudson Canal Company, where he designed the Sturbridge Lion. He retired in 1864 and died in Rome, New York, on January 12, 1885.

Land Mines

A land mine is an explosive device that is usually concealed underground and whose purpose is to destroy or disable enemy soldiers. The mines usually detonate with the application of pressure, although other means have been used, including using trip wires or lit fuses to ignite the device. The land mine can cause damage in two significant ways: either by the blast itself or by the shrapnel thrown by the explosion. Mines are generally defensive weapons, especially when the attackers' path is known or they can be funneled into a specific area.

The American Civil War is considered the first modern war in part because of its devastating and controversial new weapons, including the land mine. The land mine was perfected by Gabriel Rains (1803–1881), a Confederate officer. Union and Confederate members alike criticized this device, considering it barbarous and ungentlemanly. Despite its detractors from within the Confederacy, it became a staple in all future wars, bringing military conflicts into the modern age.

The first documented use of a pressure-detonated mine is in the *Huolongjing*, a 14th-century military treatise that recorded weapon use. A military engineer of German descent, Samuel Zimmerman, significantly improved the land mine in Europe in the 16th century in the form of the *fougasse*—an improvised mine made by hollowing out the ground and filling it with black powder and projectiles that could be detonated by pressure.

Gabriel Rains created the first mechanically fused, high-explosive antipersonnel land mines in the United States. Rains, a West Point graduate, served in Florida and Louisiana during the Second Seminole War and also recruited troops for the war with Mexico. During

his time in the United States Army, he became well known for experimenting with explosives. When North Carolina seceded from the Union in 1861, he resigned his commission as a lieutenant colonel and joined the Confederacy as a colonel, quickly moving up to the rank of brigadier general by September of the same year.

The first use of the land mine during the American Civil War came while Rains was leading troops in a retreat from the battle of Yorktown. While fighting a rear-guard action, Rains's troops buried 8" and 10" artillery shells with fuse primers. As the Union troops activated these makeshift land mines by stepping on them, panic spread and entire companies retreated. Rains quickly found more of these makeshift land mines and buried them to protect the Richmond area. Though Rains was an unsuccessful brigade commander and drew heavy criticism from Confederate commander Daniel H. Hill at the Battle of Seven Pines in 1862 for his failure to attack Union troops, he made a name for himself by developing land mine technology. As his reputation for working with explosives spread, the Confederate War and Navy Departments called upon him to discuss the use of exploding mines.

Rains started off fairly simply by filling tin cans with powder that had trigger attachments to set them off, but these offered little in the way of destructive power. Soon after, he developed a mine that could be used on both land and water that became known as the "Rains Patent." The Rains Patent mine was made of sheet iron and was filled with powder and shrapnel; it had a fuse connected to a brass percussion cap. When pressure was placed upon the mine, the cap would ignite the fuse and set it off. These mines became a useful weapon to the Confederacy, especially because it was fighting a defensive war and, more important, because the objective of the Union in the Eastern Theater was to capture Richmond. Rains believed that more than 1,300 land mines surrounded the capital by 1864.

Soon after seeing the effectiveness of the land mine, the Confederates began to use them around houses, shops, telegraph poles, and even hidden in sacks of flour. They were especially effective in guarding fortifications. Confederate soldiers defending Charleston in South Carolina, Battery Wagner, Morris

Island, Fort Sumter, Fort McAllister, and Fort Fisher used the Rains Patent land mines. The troops under William Tecumseh Sherman were plagued by land mines throughout their march to the sea in 1864. The mines became such a problem for Union forces that Sherman started marching Confederate prisoners in front of the Union columns as human minesweepers. There are no official records that Union soldiers made use of the land mine during the Civil War, because Union forces strongly opposed mine warfare and deemed it murderous and barbarous. Also, the Union army very seldom found itself in a defensive position.

Gabriel Rains, after creating the "Rains Patent," established mines for use in the water that protected the harbors of the South and deterred Union ships from traveling the waterways. Although all of his efforts were in vain for helping the Confederacy win the war, he laid the groundwork in creating an effective and deadly land mine that would be used as a template for those of future generations.

Long, Crawford Williamson (1815–1878)

Crawford Williamson Long was an American surgeon and pharmacist who pioneered the use of sulfuric ether as an anesthetic for surgery. His application for an anesthetic is a successor to Humphry Davy's use of nitrous oxide in 1800. Today, nearly all surgeons use some amount or form of anesthesia to aid them in their work.

Long was born in Danielsville, Georgia, and died in Athens, Georgia. Long studied under Benjamin Dudley, a famed surgeon, witnessing patients undergoing

surgeries without the use of sedatives or anesthetic. During his studies, Long saw the effects of hypnotism and nitrous oxide on people. Noticing that people who used nitrous oxide recreationally did not feel pain when injuring themselves, he began to use anesthetics, choosing sulfuric ether.

Anesthesia is used to enable medical procedures to be performed on patients with reduced or no pain. The three categories of anesthesia are: general anesthesia, sedation, and regional anesthesia. The first forms of general anesthesia were herbal remedies used by early humans. Alcohol has been a common and prevalent sedative used since ancient times. Experimenting on himself, Humphry Davy found nitrous oxide, which was previously thought to be lethal, to be an anesthetic.

In March 1842, he successfully removed a tumor from the neck of a young man while employing his anesthetic. Despite his success, Long did not publish his findings, as he wanted to be very sure of his work. In the December 1846 issue of *Medical Examiner*, a Boston dentist named William Morton was cited as claiming that he had used ether as an anesthetic. The subsequent, January 1847 issue presented various experiments in using ether. Long wrote up his own findings and account of his discovery and presented them to the Medical College of Georgia in 1849. While there was a controversy over who had discovered the use of ether, Long merely sought the recognition of his peers and the well-being of his patients.

In 1842, Long married Caroline Swain, with whom he had 12 children. In 1851, he and his family moved to Athens, Georgia, where he and his brother, Robert, began practicing pharmacy. During the Civil War, he served as a surgeon and treated soldiers on both sides of the conflict. On June 18, 1879, Long was declared as the discoverer of anesthesia by the National Eclectic Medical Association.

Machine/Gatling Gun

The first guns were manually loaded one round at a time, and pulling the trigger fired that round. Revolvers changed this. Revolvers loaded multiple rounds, but one pull of the trigger still only fired one round. Machines that made gun parts repeated the same task over and over. Inventors wanted to devise a gun that fired over and over: a gun that worked like a machine.

James Puckle (1667–1724) invented a single-barrel firearm that held nine rounds. Each round rotated in place and fired by means of a hand crank. It could fire 63 rounds in seven minutes. The multishot weapon that Wilson Agar invented in the 1800s could fire about 120 rounds per minute.

Dr. Richard Gatling (1818–1903) invented a weapon that could fire hundreds of rounds per minute. The multiple-shot, multiple-barrel Gatling gun was patented in 1862 (U.S. Patent 36,836).

The first Gatling guns had funnel-shaped hoppers or containers to hold loose rounds of ammunition. The gunner turned a hand crank to rotate the gun's barrels. When one of its six barrels moved past the hopper, it picked up a cartridge. Continuing to crank caused the round to fire, rotated the barrels, and expelled the empty round and picked up a loaded one. The gun fired as fast as the crank was turned and continued to fire until the crank stopped turning or it ran out of ammunition.

The Gatling gun was heavy and difficult to move. It was mounted on a two-wheel carriage and required several people to move it. Previous multiple-shot weapons overheated from repeated firing. The Gatling gun's multiple barrels dispersed the heat created when firing, so it was less likely to overheat.

Hiram Maxim (1840–1916) invented the first self-powered or automatic machine gun and patented it in 1884. The Maxim gun had a single barrel. Rounds were held in individual pockets of a cloth ammunition

A precursor to the modern machine gun, the gatling gun, also known as a rotary cannon, was used by the Union Army during the American Civil War. (Ridpath, John Clark, *Ridpath's History of the World*, 1901)

belt that fed into the gun. The first round was cocked by hand. The trigger pulled and was not released. The energy from the propellant charge explosion pushed in all directions, and the energy pushed the round down the barrel. Energy that pushes in the opposite direction is called “recoil.” The Maxim gun harnessed the recoil energy to push the empty round out of the gun and also a loaded round into place, ready to be fired. The Maxim continued to fire until the trigger was released or the gun was out of ammunition.

The Maxim gun had a unique cooling system that resembled a water jacket around the barrel. As the water

cooled the barrel, the water’s temperature increased, creating water vapor. Later models captured the vapor in a reclamation system that recycled it. Vapor was fed into a reservoir. When the vapor cooled, it returned to the liquid state and was fed back into the jacket. Maxim guns fired 500 to 600 rounds per minute.

A variation of the automatic machine gun was invented by John M. Browning (1855–1926) and patented in 1890. Browning noted the explosion of energy out to the muzzle when a round fired. Browning developed a method to capture that force. This led to the Colt Model 1895 automatic machine gun.

This gun's barrel had a small hole in the bottom muzzle end that captured some of the gas produced when the charge exploded and pushed the bullet down the barrel. The gas pushed a lever that opened the breech, and a spring forced a loaded round into place, ready to fire. Browning's machine gun was fed by an ammunition belt and could fire 400 rounds per minute.

Browning designed the gun with a thicker single barrel, so no cooling system was needed. It weighed less, so it could be mounted on a tripod. Shooters were taught to fire in short bursts instead of with prolonged, repeated fire to decrease the likelihood of overheating.

Manual machine guns weren't used much after automatics were invented. Browning's machine gun was used during World War I (1914–1918). Maxim's machine gun was modified and still in use in the 1950s. Modern automatic machine guns are variations of these models.

Mason Jar

John Landis Mason invented the mason jar in 1858. Mason jars (and jars like them) are the central piece of hardware in home canning.

While the early 19th century saw a plethora of self-sealing canning jars, most of them suffered from flaws. Tin lids lost their seal, and wax sealing was vulnerable to mold spoilage. John Mason patented a glass jar with a screw-finished neck onto which could be laid a flat lid and a screw-pressed metal ring. The mason jar rapidly became popular, particularly after Mason introduced a variety of jar shapes and glass colors. However, a glitch in Mason's patent allowed

other glass manufacturers to copy and alter Mason's design—so much so that by the 1870s, the market was flooded with canning jar types.

Charles de Quilfeldt of New York introduced the wire bale closing system, which became the most popular canning jar option of the late 19th and early 20th centuries. Wire bales affixed to the neck of jars allowed the lids to be clamped down with pressure. The seal was particularly good when used with a rubber O-ring between the lid and the neck of the jar. This type of jar is still readily available today.

Mason jars and their ilk are experiencing a renaissance in the early 21st century, given the resurgence in home canning and jar lunches.

Maynard, Edward (1813–1891)

Edward Maynard was an American dentist and firearms inventor. In 1831, he enrolled into the U.S. Military Academy at West Point but resigned due to health issues, and he became a dentist in 1835. While practicing dentistry, his clientele included congressmen and presidents, and it is reported that he declined the position of imperial dentist to Tsar Nicholas I. In 1857, Maynard became professor of theory and practice at the Baltimore College of Dental Surgery. Maynard had seven children with his first wife, Ellen, and none with his second wife, Nellie.

He was awarded 23 patents relating to firearms, the first of which was awarded in 1845 for a priming system that cycled a small mercury fulminate charge to the nipple of a percussion cap firearm. In 1845, the Maynard system was installed and successfully trialed on 300 converted percussion muskets. In 1851, he patented a simple lever-operated, breechloading rifle that

was loaded at the rear rather than from the muzzle, as his previous patent was deemed unreliable in combat.

While breechloading firearms had been invented in the 14th century, they only became more successful in the 19th century with improved precision in engineering, machining, and manufacturing. The difficulty with making reliable breechloading firearms was creating an adequate seal for the breech. This was overcome with the employment of self-contained metallic cartridges and the development of the interrupted screw.

The Maynard carbine was manufactured between 1858 and 1859 and was used in the American Civil War. Pressing on the gun's lever revealed the breech for loading, and raising the lever closed the gun's breech. It also employed the Maynard priming system. Over 21,000 of the carbine's various models were built.

In 1857, Maynard founded the Maynard Arms Company with the help of financial backers. He contracted the Massachusetts Arms Company to manufacture Maynard carbines for both civilian and military use. While the Maynard was acclaimed in frontier service, only four U.S. regiments were armed with the first model during the American Civil War. In January 1861, the Massachusetts Arms Company's factory burned down, possibly contributing to the relatively low rate of distribution. In 1888, he held the chair of dental theory and practice at National University in Washington, D.C. Maynard died on May 4, 1891. He is buried at the historic Congressional Cemetery in the District of Columbia.

Maynard Carbine

The Maynard carbine was a popular firearm that utilized a breechloading design that replaced the flintlock. It was considered one of the best-performing and most accurate carbines of the American Civil War era. Two models of the Maynard carbine were produced. The first was simply known as the "First Model," with approximately 5,000 produced between 1858 and 1859. The "Model 1863" saw production of about 20,000 between 1863 and 1865 amid the American Civil War (1861–1865).

Inventor and dentist Dr. Edward Maynard (1813–1891) was credited for many patents in the field of dentistry and firearms in his time. Shortly after his resignation from the U.S. Military Academy at West Point in 1831, Maynard began pursuing the profession of dentistry in 1835. As a natural mechanic and skillful welder, Maynard took great pride in his ability to make his own dental instruments at a time when standardized equipment was not yet established. His dental practice would land him in Washington, D.C., where his clientele grew to include distinguished members of the country's political elite. Tsar Nicholas I asked him to become the imperial dentist after the emperor's surgeon witnessed an operation performed by Maynard. He declined the offer and continued his practice in Washington, D.C., for the rest of his life. Maynard would go on to accept the chair position for Theory and Practice of Dentistry at the Baltimore College of Dental Surgery from 1856 to 1860, and he later accepted the same position in the faculty of the Dental Department of the National University at Washington from 1887 to 1889. He was also the recipient of several honorary degrees such as an AM from Columbia College in Washington, D.C., an MD from Western Medical College in 1840, and a DDS from the Baltimore College of Dental Surgery in 1841. Maynard died on May 4, 1891, at the age of 78 from Bright's disease, which involves inflammation in the kidneys. He had retired from his practice as a dentist a year prior due to failing health. He had been married to Ellen Sophia Doty of Sherburne, New York, in 1837 and had six children. She would later die on October 3, 1863, in Cooperstown, New York. Six years later, he

wedded Nellie Long of Savannah, Georgia, in 1869, and they had one daughter together.

Despite his contributions in the field of dentistry, Maynard is best known for his contributions in firearms. One in particular was his breechloading rifle design in the Maynard carbine that he patented on May 27, 1851. It is a single-lever operated design that primarily fired a 0.52-caliber metallic cartridge. The lever operated the breech for loading the weapon. Depressing and raising the lever opens and closes the breech. A major issue to overcome at the time in the early development of breechloading rifles was escaping gas at the breech, but Maynard's use of a metallic cartridge and a slight gap between the breech and the receiver helped seal the gas in.

There were two versions of the Maynard carbine: the "First Model" and the "Model 1863." Production of the First Model was made possible after successful army test trials on May 16, 1856, sparked the interest of several to form the Maynard Arms Company of Washington, D.C., in April 1857. Through the Massachusetts Arms Company, 5,000 First Models were manufactured and appeared on the market from 1858 to 1859. They had a patch box in the stock and Maynard's tape primer system. Another 400 were purchased from the secretary of war for U.S. Army use after a second army test trial. The Revenue Cutter Service (a.k.a. the U.S. Coast Guard) and the U.S. Navy followed suit with 100 and 50 respectively. Although 400 were purchased, between 1861 and 1863, only the 1st (later 4th) U.S., 9th Pennsylvania, and 1st Wisconsin Cavalry were ever issued the First Model.

On January 28, 1861, the Massachusetts Arms Company's factory was destroyed by fire. It was later rebuilt in 1863 and produced the second version of the Maynard carbine. Between 1863 and 1865, 20,000 units were built. This model was equipped to take the more traditional percussion caps that proved to be more reliable than Maynard's system, and it lacked the patch box in the stock and also the tang sight that was used on the First Model. Delivery of the Model 1863 to arm the federal cavalry began in June 1864 and continued until May 1865. Despite being issued late in the war, the 9th and 11th Indiana regiments, along with the 11th Tennessee Cavalry, were partially equipped

with the Model 1863. The rest saw little or no service and were left in arsenals until they were sold off by the government in the late 1860s. Use of the Maynard carbine was not limited to Union forces.

Prior to Abraham Lincoln's election to president in November 1860, the First Model was purchased by Southerners for sporting purposes. Approximately 1,500 of 5,000 First Models were purchased from the Maynard Arms Company a month before Lincoln took office. The remaining inventory was sold off six months following the 1860 election. Over 90 percent armed the Southern militia companies that were forming throughout the states of Mississippi, Florida, and Georgia. The Maynard Arms Company also entered into contracts with two Mississippi senators for 800 First Model carbines on December 20, 1860, and 1,000 more with the state of Georgia on December 18, 1860. Louisiana and South Carolina also purchased the firearm prior to the start of the Civil War. The number of First Models in soldiers' hands only grew with Confederate forces seizing control over federal arsenals located in the Southern states. Indeed, the First Model was listed as an official firearm in Confederate ordinance manuals.

Cartridges for the carbine were simple to make, which proved to aid Confederate forces, as the South lacked complex manufacturing facilities. The popularity of the rifle came with its ease of use, maintenance, and simple construction. Praised for its accuracy by Confederate sharpshooters, the folding rear sight allowed the user to fire at 100, 200, and 300 yards once aligned with the forward post sight. Trained marksmen had been known to hit their targets at 600 yards at nearly 12 rounds per minute. It was relatively compact at 40 inches long with a 20-inch barrel.

Production continued through the Massachusetts Arms Company beyond the conclusion of the Civil War in 1865. By then, special accessories allowed the carbine to be converted to chamber a thick based Maynard centerfire cartridge. Gaining high regard as a centerfire target and hunting rifle, Dr. Maynard's design outlived many other Civil War carbines. The 1890s saw several changes that ended the production of the Maynard carbine. The rising popularity of the repeating rifle and the changing climate in manufacturing practices may have

caused the bankruptcy of the Massachusetts Arms Company, resulting the demise of the Maynard Carbine.

McCormick, Cyrus (1809–1884)

Cyrus McCormick was an inventor and businessman whose creations and innovations changed the face of 19th-century American farming. The mechanically adept McCormick left his life as a farmer and turned to inventing. The products of his work, coupled with his business acumen, were critical to the development of the nation's agricultural heartland, and the sum of his efforts ultimately served to revolutionize the American agricultural landscape. In particular, his invention and development of the mechanical reaper changed the nature of agriculture in the heartland, allowing farmers on the new frontier to move beyond single-family farms and to profit from increasingly large farms.

Cyrus McCormick was born on February 15, 1809, in Rockbridge County in the Shenandoah Valley of Virginia. The oldest of eight children born to Robert McCormick and his wife, the former Mary Ann Hall,

McCormick received little formal education. However, from an early age, he liked to tinker in his father's workshop on the family farm. Indeed, at only 15 years old, he came up with the idea for a cradle to transport grain. That invention would prove to be only his first that would ultimately change the face of farming. His greatest invention, the reaper, represented not only his impressive mechanical and engineering skills but also his perseverance, for he developed it in part out of early experiences and some preliminary designs over which his father had toiled for a number of years. By adding his own mechanical input and ideas, in 1831, McCormick first demonstrated not only a viable piece of farm machinery but a revolutionary one. While the initial model, demonstrated for the first time in 1831, did not adapt well to varying conditions, McCormick quickly fixed that problem, and in 1834, he secured a patent.

The young inventor then undertook the challenge of convincing a skeptical population of farmers of the value of his reaper. The need to make it viable commercially was heightened when, in the aftermath of the Panic of 1837, the McCormick family foundry failed. This led Cyrus to put an even greater focus on the reaper. Slowly, as knowledge of the new invention spread, it became marketable, and sales grew from 2 in 1841 to 7 in 1842 to 29 in 1843 and a burgeoning 50 in 1844. The following year, McCormick secured a new patent on an improved reaper, and in 1847, forming a partnership with Chicago Mayor William Ogden, who provided the major funding, established a factory in the city and, by the following year, sold 800 reapers. Sales continued to grow, and McCormick was soon able to buy out Ogden. However, as distribution widened, so did those who copied the design. As the time came to renew his original patent, McCormick found himself mired in ongoing and hard-to-win patent battles.

Recognizing the difficulty of obtaining the exclusive rights to his product, he instead turned to some unusual and innovative business practices to secure his fortune and establish his place at the forefront of the farm machinery business. Taking advantage of the growing railroad network crisscrossing the nation, McCormick advertised extensively and dispatched high-publicity salesmen who, traveling widely, got into local communities where they educated farmers

about the benefits of the new technology and offered public demonstrations of it. In addition, McCormick offered product warranties and written guarantees while also developing a system of mass production that helped make replaceable parts easily available. Also, in an effort to get his machine into the fields, since that would serve as its best form of marketing, McCormick offered lenient credit for purchasers.

Soon, the McCormick Reaper was known and used across the country, and that success was followed soon afterward by its introduction in Europe. Indeed, in 1851, McCormick introduced his machine at the Great Exhibition in London, where it was awarded the grand prize. Four years later, McCormick emerged triumphant from the French International Exposition, with the reaper earning the Grand Medal of Honour. By 1856, the McCormick Harvesting Machine Company—which, under the leadership of his son Cyrus McCormick Jr., would eventually become International Harvester—sold 4000 machines.

When the company's factory was a victim of the 1871 Chicago fire, McCormick's wife urged him to rebuild, and in 1873 a new, larger factory was opened. As the company thrived, McCormick, a notorious workaholic, began to turn some of his considerable energies to civic and philanthropic endeavors. He was an active and longtime supporter of the Presbyterian Church and was also the principal supporter and member of the board of trustees of the McCormick Theological Seminary in Chicago. In addition, McCormick was an active supporter of the Democratic Party. Retaining ties to his native Virginia, McCormick was

a generous financial supporter of Washington and Lee University while also serving as a trustee for the last 20 years of his life. A statue of McCormick was later erected on the university's front campus.

While he had struggled in the beginning to convince people of the value of his work, by the end of his life, he was being honored in numerous venues, including election as a corresponding member of the French Academy of Sciences in recognition of his having done so much for the cause of agriculture.

McCormick had married his one-time secretary, the former Nancy "Nettie" Fowler, in 1858. The couple had seven children. In 1880, he turned control of the company over to his son Cyrus Jr. The active and vigorous McCormick suffered a stroke in 1880 that left his legs paralyzed for the last four years of his life. Cyrus McCormick died on May 13, 1884, at his Chicago home. He is buried in Graceland Cemetery.

Primary Document: Letter of Robert E. Lee to Cyrus McCormick Regarding the Curriculum at Washington College (1865)

Immediately after his surrender in April 1865, Robert E. Lee took the job of president of Washington College. Cyrus McCormick made a gift of money to the college, which then instituted a shift in curriculum from pure classical education to one that included science and technology classes. The following is the letter that Lee wrote to McCormick about the educational shift at the college.

Washington College
 Lexington VA: 28 Nov 65

Sir

At a late meeting of the Board of Trustees of Washington College, it was resolved, with a view to a more thorough & extended course of scientific instruction; & to the liberal & practical education of the industrial

classes; to establish five additional Professorships; without interfering with the regular classical & literary course.

The Professorships proposed are those of Practical Chemistry, Experimental Philosophy & practical mechanics, Applied Mathematics, Modern Languages, History & Literature.

Such a course of instruction, is requisite to meet present events of the country; & enable those young men who do not desire to devote themselves to special professions, requiring specific studies after graduating, to enter at once upon the active pursuits of life. To you who are so conversant with the necessities of the country, & its vast underdeveloped resources; the benefit of applying scientific knowledge & research, to agriculture, mining, manufacturing, architecture, & the construction of ordinary roads, R. Roads, canals, bridges etc., will be at once apparent; & it is hoped will elicit your approval. To provide the funds necessary for the execution of this project, the Board of Trustees rely upon the patriotism of the people; & the citizens of Rockbridge &

adjacent counties, notwithstanding their impoverished condition; are responding with generosity, which they always evince towards measures of national importance. Their efforts I am sure, will be strengthened by your sympathy; & your influence will cheer them in their meritorious work. The success of their cherished design, I am equally sure, will be peculiarly gratifying to me, who has already done so much for the advancement of agriculture & the relief of the husband-man; not only of his native state, but for a grateful world; & it is this consideration that has emboldened me, to bring it to your notice.

I am Sir with great respect

Your obt servt
R E Lee

Mechanical Reaper

Invented in 1831, Cyrus McCormick's mechanical reaper changed the face of American agriculture. A product of years of work that actually had been started by McCormick's father on their farm in Virginia, the reaper had an incalculable impact on both farming and the national economy.

Prior to the invention of the reaper, American farmers had harvested grain through a manual process dating back to the beginning of agriculture. Farmers would cut the standing grain by wielding a hand-swung scythe and were followed by another set of workers, the binders, whose job was to tie the cut grain into bales that were carted away and stored, generally in barns. This onerous process required more labor than did the actual planting. Consequently, the amount of acreage that could be planted was limited by the harvesting process.

It was this problem that McCormick's reaper addressed. The machine's roots could be traced to the longtime interest of Robert McCormick, Cyrus's father, in developing a method for harvesting more

and doing it faster. After years of work trying to develop the appropriate tool, he abandoned the project in 1831, only to have the mechanically adept Cyrus step in and adapt and develop his father's basic work in a way that made agricultural history. Indeed, once he had the idea sketched out, it took less than two months to build and field-test a prototype.

In its original form, the reaper could increase a farmer's yield by 10 times with comparatively little effort by the attendant farmer, and while the initial model first demonstrated in 1831 did not adapt well to varying conditions, McCormick quickly fixed the problem. Despite the way the reaper streamlined the labor-intensive process of cutting, threshing, and bundling grain, all while being pulled by a horse, it would be almost a decade before farmers began to buy it. But in that intervening time, McCormick continued to work on his creation, fine-tuning its operation—the early version was particularly noisy and required a person to walk alongside to calm the horses.

In 1834, McCormick received a patent for his mechanical reaper. In an effort to create a market for

the machine, McCormick undertook some innovative business practices. Taking advantage of the nation's growing railroad usage, he sent salesmen out into the community, arranged demonstrations, and offered written guarantees and lenient credit for purchasers while also making replaceable parts easily available.

In the early 1840s, the idea of a mechanized reaper took hold, and in 1845, McCormick secured a new patent on an improved reaper. In 1847, he built a factory in Chicago, and the next year, sales reached 800. In the early 1850s, McCormick introduced the reaper in Europe, where it won awards at expositions in London and Paris. Despite continuing patent battles, sales on both sides of the Atlantic boomed.

Meanwhile, McCormick continued to refine his creation. In 1872, the company produced a model that automatically bound the bundles with wire, and in 1880, it began selling a binder that used a knotting device that bound bundles with twine.

While the reaper would eventually give way to the self-propelled combine, it nevertheless was a critically important first step in the direction of mechanized farming. It revolutionized farming while significantly impacting the American economy.

Merrick, Solymon (1806–1852)

Solymon Merrick patented the first wrench in 1842. Wrenches tighten bolts and screws much tighter than someone can do it by hand. Merrick's patent helped pave the way for multiple job industries to flourish, as it allowed for a unified system to be created for screws

that were used to tighten bolts, as well as equipment used in numerous industries. Before the wrench was called a wrench, it was known as a "spanner."

Solymon Merrick was born into a free black family in 1806 in Massachusetts. He probably developed the wrench in 1835, but he didn't patent his design until 1842. Other inventors followed suit, creating different types of wrenches such as the monkey wrench, ratchet, and pipe wrench. This cropping up of new and unique types of wrenches shows how revolutionary Merrick's invention was, since there was no readily available substitute.

The wrench that Solymon design had a slanted head, which meant that the user could set the wrench in place at an odd angle and rotate it to correct the angle. The bent neck functioned as a kind of built-in user's manual.

In his lifetime, Merrick filed 11 patents, all of them between 1834 and 1851. Seven of them are for wrenches, including a quick-adjust wrench and several nut wrenches, but he also patented two leather punches and a machine for making barrel staves. He died in 1852 in Springfield, Massachusetts.

Charles Moncky invented the monkey wrench in 1858, while Daniel Stillson invented the pipe wrench in 1870. Robert Owen Jr. patented the ratchet wrench in 1913. The wrench has arguably been one of the greatest but most unappreciated inventions of the 1800s and is an international symbol for the handyman.

Military Technology (Civil War)

The technological advancements that were made during the American Civil War are why many historians consider it first modern war. The most significant advancements took place in weaponry, but there were

others in medicine, photography, the telegraph, submarines, locomotives, and many more fields.

Of all the technological advancements, changes in weaponry affected the average soldier the most. The tactics used during the Civil War were the same as in previous generations, but the weaponry became exponentially better, creating extremely high battlefield death tolls. The first weapons used were primarily smoothbore muskets, which had an approximate effective firing range of 80 yards. As the war progressed, the smooth bores were phased out and the rifled musket took its place. The rifled musket used the minié ball, a soft, conical lead bullet with rings that would expand to fit the rifling of the musket, therefore increasing its accuracy at 300 yards. “Rifling” refers to the helical grooves in the barrel of a gun that causes a bullet to spin, helping it to travel farther. The extended range of a rifled gun could be up to a half mile. The new rifled muskets also improved the rate of fire to approximately three rounds per minute by a trained soldier. With the large amount of new recruits filling the ranks of both the Union and the Confederate Armies, they were trained in tactics primarily with the smoothbore musket in mind. These relied on massed fire and condensed troops, making the switch from the smoothbore to the rifled musket much more devastating.

The Civil War was the first war to make use of detailed reports of medical history. Great care was taken to make notes on what worked and what did not, as well as to make records of injuries and the medical procedures that took care of them. This led to the publication of *Medical and Surgical History of the War of the Rebellion*, an early and important accomplishment in the field. In the first major battle at Bull Run, Virginia, the Union hospitals saw over 1,124 wounded, and the Confederate hospitals over 1,582. It was clear at this point that there had to be a system to handle mass casualties. Systems were quickly put in place that included field hospitals, aid stations, and permanent hospitals.

This was the first system ever set up to determine the severity of wounds and put operative procedures in place to take care of them. One of the major operations was amputation, and it was deemed best to do this within the first 24 hours of a wound for the best possible outcome. These systems and the early treatment of

soldiers were used as the template for treating soldiers during World War I, World War II, and the Korean War.

Another major finding of the Civil War was the correlation between disease and unsanitary conditions. English nurse Florence Nightingale’s work in the Crimean War in the decade before the American Civil War led her to conclude that sanitation and hygiene prevented infection, disease, and death among troops in the field and in hospitals. Civil War medical personnel were trained with these new ideas and standards in mind.

Surgical principles quickly advanced with the prevention and treatment of infectious disease with anti-septic agents, as well as the use of chloroform to reduce patients’ suffering. One of the biggest contributions to the future of the medical field was the U.S. Sanitary Commission. This was a private relief agency created by federal legislation on June 18, 1861, to support sick and wounded soldiers of the U.S. Army during the war. The Sanitary Commission was a civilian-organized and largely female-run soldier’s relief society that set the pattern for the development of the American Red Cross.

Although photographs of earlier conflicts do exist, the American Civil War was the first war to be extensively documented in photographs. Photographers traveled to the fields of battle and took pictures of the carnage there. The newest technology, wet-plate photography, involved a six-step process that included making a mixture called “collodion.” It contained ethyl ether and acetic or sulfuric acid. The photographer coated the glass plate in collodion, immersed the plate in silver nitrate in a dark room, and placed it in a light-tight container that was then put into the camera. The cap of the camera would be removed for two to three seconds, and once the image was captured, the plate was removed, taken to the darkroom, and developed. Special mixtures were used to make sure the image would not fade, and then the image could be printed to paper.

The telegraph, invented in 1844 by Samuel Morse, gave political leaders the ability to get near-instantaneous updates from the battlefields during the American Civil War. The usefulness of the telegraph was so apparent that during the war, over 15,000 miles of telegraph cable was laid for military purposes.

A telegraph works by sending a series of electric pulses through a long wire to another telegraph device, which then interprets the pulses into a series of clicking sounds. There is an “alphabet” called Morse code that the person on the other side of the telegraph can use to decipher the transmission according to how long the clicks are. Prior to the telegraph, messages had been carried by courier and took days or even weeks to get to their destinations. Military leaders were left to their own devices as to objectives as battles grew in intensity. Abraham Lincoln used the telegraph to bolster the confidence of his generals as well as to propel his leadership vision to them. Most important, he used it as a tool to gather information and understand what was going on in the headquarters of his military leadership. Not only did it allow him to be in contact with his military leaders, it also allowed the generals to communicate to one another over vast distances.

The Confederacy also made use of the telegraph, although not to the extent that the Union did. In the Eastern Theater, Robert E. Lee was constantly on the move, traveling hundreds of miles to Maryland and Pennsylvania, and he quickly moved out of range of the telegraph wires. Both sides destroyed telegraph lines and also tapped them to try to decipher the messages of their opponents.

The American Civil War also encouraged submarine development. Up to 20 working submarines were built by both sides during the war; however, most were undocumented. The most noteworthy from the period are the Union’s USS *Alligator* and the Confederacy’s *H. L. Hunley*. The *Alligator* was designed by French engineer Brutus de Villeroi (1794–1874) and was first launched on May 1, 1862. It included innovations like compressed and filtered air for its crew of 12. Just like the *Hunley*, the submarine was manually propelled. Unfortunately, *Alligator* was lost in a storm off Cape Hatteras on April 1, 1863, while being towed to Charleston for its first combat deployment. The *Hunley* had a test run in July 1863, that successfully attacked a coal flatboat in Mobile Bay. It was then shipped to Charleston and turned over to the Confederate Army.

A crew was assembled to make the first test dive, and one of the crewmen accidentally stepped on the lever that controlled the dive planes—causing the

Hunley to dive with the hatches open. Five of the crewmen drowned, and the *Hunley* ended up being recovered. The only successful attack came on February 17, 1864, against the USS *Housatonic*. The *Hunley* embedded its spar torpedo in the hull of the *Housatonic*, and as the submarine backed away from the ship, the torpedo detonated. The *Housatonic* sank in five minutes, and the *Hunley* sank to the bottom, not to rise until August 8, 2000. Although the USS *Alligator* and the *H. L. Hunley* made no great impact during the Civil War, they set the precedent for future generations of subs. The submarine was used widely during both World War I and World War II with great success.

During American Civil War, the railroads were second only to waterways when it came to transportation of troops and supplies. During the war, soldiers, material, and food were routinely transported by rail along with civilians and the raw materials necessary to keep the war effort progressing. Because the railroads supplied the units that were on campaign, they often became military objectives. One of the main factors in the eventual domination of the railways by the Union was the industrial power of the North, which was more industrialized than the South in part because the South relied on a slave-based labor force to create an agricultural economy.

The importance of the railroad appeared in the first major battle of the Civil War at the first Battle of Bull Run on July 21, 1861. A large and unprepared Union Army under the command of General McDowell moved south out of Washington, D.C., toward the rail center of Manassas, Virginia. A smaller and equally unprepared Southern force under the command of General P. G. T. Beauregard blocked this advance when Generals Joseph Johnson and Thomas J. (Stonewall) Jackson arrived from the Shenandoah Valley with their armies, using a rail line to speed their arrival at the front. This was the first significant use of a railroad in moving troops to battle, and it was extremely successful.

Union forces made it a priority to destroy railroads as they took the war through Mississippi, South Carolina, and Georgia. The destruction of the Confederate railways prevented easy transportation of troops to the front lines. Many of the Confederate railroads were captured and used by the Union to supply Grant’s

beleaguered, half-starved troops, and this allowed them to gain victory in the Battle of Chickamauga and Chattanooga. Later toward the close of the war, during the siege of Richmond and Petersburg—separated by only 25 miles—Grant provisioned his troops from an enormous rail depot at City Point. This rail junction proved useful in that the Union Army would have needed to rely on wagons and horses to supply it. Without the use of this important rail system, it was possible that the sieges could have failed and ultimately led Grant to release his stranglehold on the Confederacy.

The Pacific Railway Act of 1862 promoted the construction of the Transcontinental Railroad in the United States by authorizing bonds and grants of land to the different railroad companies involved. Lincoln signed this law because it helped in the construction of railroad and telegraph lines from the Missouri River to the Pacific Ocean. The act also secured the government's ability to use these same lines for postal, military, and other purposes. The act placed all employees and officers under military authority and was the precedent for the U.S. Railway Administration of World War I and government influence on railroads in World War II. During the Civil War, there were approximately 36,000 miles of track compared to today's 250,000 miles. The train systems throughout the United States are still relied upon to ship goods, people, military equipment, and more.

Mitchell, Maria (1818–1889)

Maria Mitchell was the first American astronomer to discover a “telescopic” comet—a comet too far away to see with the naked eye but detectable with a telescope. For her achievement, she was rewarded with a gold medal by the king of Denmark, became the first female member of the American Academy of Arts and Sciences, and later became a professor of Vassar College, one of the first exclusively all-women colleges in America.

Maria Mitchell was born on Nantucket Island, Massachusetts, in 1818. Her father, William Mitchell, was an accomplished amateur astronomer and encouraged her education, especially in math and science. At 18, she began work as a librarian at the Nantucket Atheneum by day, but at night, she would “sweep” the skies with her father for celestial objects in a small observatory he built.

On October 1, 1847, the 29-year-old Mitchell discovered a comet through her telescope. Not only was she the first American to discover a comet, but it was the first one detected with only a telescope. Even more impressive, she found it with only a tiny, two-inch telescope—demonstrating her skills as an astronomer to identify objects in the night sky. Many years before, the king of Denmark had offered a prize to whomever could find such a comet. While several astronomers spotted the comet, it was ruled that Mitchell was the

first to find it, and so she was awarded the gold medal for her achievement.

Nineteenth-century women's rights activists in Boston were proud of Mitchell, and with the support of several activists, including botanist Elizabeth Agassiz and publisher Elizabeth Peabody, Mitchell was elected into the American Academy of Arts and Sciences in 1848. She was the first woman to become a member and would be the only one for 100 years. She was also elected into the American Association for the Advancement of Science, which had recently formed and is today the publisher of the prestigious *Science* journal.

Mitchell returned to her life in Nantucket as a librarian, but the U.S. Coastal Survey paid her to sweep the skies now. Her task was to help develop weather forecasting and to measure and compute distances. People who did this became known as “computers.”

In 1865, she accepted a teaching position at Vassar College in Poughkeepsie, New York, one of the first colleges for women in the United States, though she was the only female professor out of the nine initially employed. With her father, she operated a 12-inch telescope at the school's observatory—the third largest in the country—and lectured her students at night with it. In a time when most colleges simply educated their students, Mitchell conducted original research with them; she brought them along to measure the 1869 total eclipse of the sun in Burlington, Iowa, and again in 1878 near Denver, Colorado. She also invented a device to take pictures of the sun, and her original engraved photograph plates were rediscovered in 1997. Notable inventors of the day, including Samuel F. B. Morse, corresponded with her.

As she aged, she became much more involved with politics and women's suffrage. Leading up to the Civil War, she swore never to wear cotton grown by slaves. At Vassar, she hosted “dome parties” in her observatory to discuss politics with her students and other activists and suffragists. Mitchell also led the creation of the American Association for the Advancement of Women (later renamed the American Association of University Women) and served as its president in 1873. Her list of friends included the likes of Elizabeth Cady Stanton, Susan B. Anthony, Elizabeth Blackwell, and many other activists.

As the first professional female astronomer in the United States, Maria Mitchell inspired countless young women to study science. Though relatively unknown today, her discovery of a new comet in 1847 made her internationally famous. (Kendall, Phebe Mitchell (compiler). *Maria Mitchell: Life, Letters, and Journals*. Boston: Lee and Shepard Publishers, 1896)

She retired and left Vassar in 1888, much to the dismay of her beloved students and in spite of the generous offer from the school to keep her residence and continue her research. She moved in with one of her sisters in Lynn, Massachusetts, and lived there until her death a year later from a brain disease. She was inducted to the Hall of Fame of Great Americans at New York University in 1905 and again into the National Women's Hall of Fame in Seneca Falls, New York, in 1994. When astronomers mapped the surface of the moon, they named a crater after her.

Morse, Samuel F. B. (1791–1872)

Samuel Finley Breese Morse was the inventor of the telegraph as well as an outstanding American artist in the first half of the 19th century. Indeed, while Morse's artwork, especially his painting, earned him much praise, it was his invention of the telegraph, coupled with his role in developing the Morse code, that not only had a revolutionary impact on the United States in the decades before the Civil War but also played an important role in the conduct of the war itself.

Samuel F. B. Morse was born on April 27, 1791, in Charlestown, Massachusetts, the oldest child of Jedidiah Morse, a minister, and his wife, the former Elizabeth Breese. He attended Phillips Academy in Andover, Massachusetts, before going on to Yale College—from which he graduated in 1810 with a middling record but a deep interest in both art and electricity, the latter based upon a series of lectures he had attended. After his graduation from Yale, Morse, with grudging parental approval—his father, initially insisting that he pursue a trade, had arranged an apprenticeship with a local book publisher—traveled to Europe to pursue his art, studying at the Royal Academy of Arts in London. He adopted the European style for his painting, especially the renditions that highlighted historical events and personalities against bright colors. During his time abroad, Morse achieved some minor artistic success, and in 1815, he returned to the United States, still intent upon pursuing his painting career. Morse set up a base of operation in New Haven, Connecticut, although he traveled throughout New England and the Northeast and even ventured into South Carolina, seeking commissions. He achieved moderate success, receiving commissions to paint former president John Adams and President James Monroe as well as a number of other wealthy merchants and political figures. In addition to the portraits, he also painted a series of works that depicted the workings of the government. While they were not much appreciated at the time, they later decorated the halls of Congress and, like his portraits, they gained greater appreciation with time.

On September 29, 1818, Samuel Morse married the former Lucretia Walker. Together they had three

children, a girl and two boys. She died on February 7, 1825. Over two decades later, on August 10, 1848, Morse remarried, this time to the former Sarah Elizabeth Griswold, with whom he had four more children: three sons and a daughter.

In 1825, after the death of his first wife, he moved to New York City, where he assumed the presidency of the newly formed New York Drawing Association. The following year, he was a founder and the first president (a post he held for the next 19 years) of the National Academy of Design, an organization seeking to increase the nation's respect for its painters. In 1827, he helped launch the *New York Journal of Commerce* while also publishing *Academics of Art*.

In 1832, his longtime continuing interest in electricity led him to begin developing the idea of an electric telegraph after overhearing a conversation about the newly discovered electromagnet. While Morse believed his idea was original, in fact, the concept had been proposed as early as 1800, but the artist-turned-inventor pursued it nevertheless, making his first working model around 1835. Throughout this period, he continued to pursue his art and was also teaching at the University of the City of New York (later New York University). He also dabbled a bit in politics, running as an anti-Catholic and anti-immigrant candidate for mayor in 1836—and again in 1841. However, despite these other diversions, by 1837 he was focused on the development of his telegraph, teaming up with a colleague at the university, chemist Leonard Gale, and his friend, Alfred Vail. In 1838, Morse and Vail developed the system of dots and dashes that would become Morse code, but they were unable to convince Congress to undertake the construction of a telegraph line. Turning their attention to Europe, they sought the construction of a telegraph line on that continent, but that effort too was rebuffed. While his former partners abandoned the project, Morse continued his efforts to make a telegraph network a reality. Finally, in 1843, Congress gave Morse sufficient financial support to construct the nation's first telegraph line—one that went from Baltimore to the nation's capital. Completed in 1844, on May 24, Morse sent the first message: "What hath God wrought."

With telegraph communication a reality, Morse was soon the focus of a flood of legal claims from his

former partners and competing inventors over the rights to the invention and the inevitable profits that would flow from its development. These battles culminated in an 1854 decision by the U.S. Supreme Court that established Morse's patent rights. Meanwhile, as telegraph lines spread across the United States and Europe, Morse's wealth and fame also grew, and the one-time itinerant painter bought an estate, Locust Grove, overlooking the Hudson River near Poughkeepsie, New York. There he built a mansion designed in the style of an Italian villa. The site became the family's summer home, a retreat from their New York City residence.

The wealthy Morse spent his last years as an active philanthropist. He helped found and fund Vassar College in Poughkeepsie and also served on the college's board of trustees. He also gave generously to his alma mater, Yale, while a variety of churches, theological seminaries, and Bible societies also benefited from his generosity. So too did assorted missions and temperance societies, as well as the many struggling artists whose efforts he helped support.

With his 81st birthday approaching, Samuel F. B. Morse died on April 2, 1872, in New York City. He is buried in Green-Wood Cemetery in Brooklyn, New York.

Morse Code

Although nowadays the Morse code has come to be largely restricted to amateur communications and radio aficionados, for over a century, it was the most widely used system for transmitting communications. Thanks to it, text information could be easily and effectively conveyed regardless of distance.

The Morse code makes use of signals of different duration in order to transmit information. There are short signals, called "dots," and longer signals called

"dashes." A given character is a unique combination of dots and dashes, each dash having a three-dot duration. Every dash or dot is followed by a silence with the duration of a dot. Also, each letter is followed by a silence with the same duration as a dash, while every word is followed by a seven-dot silence.

The Morse code was named after its inventor, Samuel Finley Breese Morse (1791–1872). A Yale graduate, Morse's real passion was art, which his father at first discouraged. Eventually, his father relented, and Morse traveled to England to pursue an artistic career. However, Morse's creativity also found an outlet in designing and inventing and, along with his brother Sidney, he created a machine to cut marble. The brothers also got three patents for water pumps.

But the invention for which he would become world famous and make his name a byword for communication would not materialize until later in his life. Developing a system that could quickly transmit information over long distances was an issue that touched Morse very deeply. In 1825, his wife had died in New Haven, Connecticut, while he was away in Washington, D.C. However, a letter bearing the news did not reach him until a week later, when the funeral had already taken place.

Morse's interest in electricity dated from 1827, but he first thought of an electromagnetic telegraph in 1832 while traveling from Europe to the United States. He conceived the idea of an electrical current that could transmit information by means of a wire. It would not be until 1836, though, that he succeeded in bringing his idea to fruition. Morse worked closely with science professor Leonard Gale, making use of Joseph Henry's previous invention based on William Sturgeon's electromagnet. At first, Morse faced years of poverty and even derision, as a failed public demonstration made of him the butt of many jokes. In 1837, Alfred Vail attended a display of Morse's invention and was attracted to the idea. Vail's father agreed to finance Morse and host the project in his factory in exchange for his son's participation. In 1843, the American government gave Morse a grant to pursue his research. He used the funds to set up a telegraph line between Baltimore and Washington. On May 24, 1844, he transmitted the first message—"What hath God wrought," a biblical quotation from Numbers

23:23, which had been chosen by a minister's daughter.

The widespread popularity of the telegraph made Morse a well-known and wealthy man, although it also brought him its share of problems. Among these, the most serious involved accusations of plagiarism and intellectual theft. In 1837, the U.S. Supreme Court ruled that Morse reached the most perfect result for public and practical use.

The International Morse Code is a variation on the original code invented by Vail and Morse in 1835. Morse first imagined the code as consisting of a combination of numbers, with each unique combination assigned to a word. The first changes were introduced by German Friedrich Clemens Gerke in 1848. Standardized at the International Telegraphy Congress in Paris in 1865, it is known as International Morse Code or "the continental code" in contrast to the Morse code used in the United States and Canada and known as American Morse or "railroad code."

Of the most famous uses of the Morse code is "SOS," the distress signal. First used in 1905 by the German government, although popular belief attributes the SOS signal to an acronym for "save our ship" or "save our souls," it stands for no message. The Morse code proved to be vital during the Second World War, with some modifications to attempt to conceal messages. The advantage of using Morse code is that even in poor conditions, it can be comprehensible. Not only was the code used in telegraphic communication but also in radio systems, aviation, and across undersea cables.

Morse code was in use for maritime communication until 1999, when the Global Maritime Distress Safety System replaced it. The last official use of the Morse code in the United States was on July 12, 1999. The last message transmitted was "What hath God wrought."

National Academy of Sciences (NAS)

The National Academy of Sciences (NAS) is a society of scientists, scholars, engineers, and other distinguished researchers. The organization was founded on March 3, 1863.

In the midst of the Civil War (1861–1865), the U.S. Congress created the National Academy of Science (NAS), composed of 50 original members. The NAS partnered with the National Academy of Engineering and the National Academy of Medicine to act as an advisory council to the president of the United States and help protect the public through research and by creating new standards for and advancements of safety in each respective field. Today, the National Academy of Sciences includes members from all over the country and supports the work of national institutes and laboratories. The NAS gives scholarships and awards to members with outstanding work to help support their ongoing research. It is not about the importance of any one person or a particular discovery or work but rather to support scientists and researchers who strive to improve society.

Of the almost 3,000 NAS members, approximately 200 have been awarded Nobel Prizes. This award is arguably the single most prestigious that anyone who contributes notably to society can receive—but even just being nominated to join NAS is a remarkable honor in itself, because the society accepts only the most elite contributors. For example, Frederick Sanger, a biochemistry researcher, helped discovered how to sequence mRNA and DNA. His work led to two Nobel Prizes in chemistry. His major breakthrough became the foundation of identifying genes that correlate to specific diseases as well as gene therapy, revolutionizing the way the medical field approaches a problem. Due in part to Sanger's work, we can customize medicine uniquely for an individual's genes.

Another National Academy member, James Tiedje, was the president of the American Society for Microbiology from 2004 to 2005; his research has been based on analytical experiments on the microbiology in soils necessary to sustain life. His tests were later used to test the hypothesis that life can be sustained on Mars.

Other notable contributors include Robert Oppenheimer, the "father of the atomic bomb," Stephen

Hawking for his work in theoretical astronomy that help us better understand the dynamics of the solar system, and Michael Goddard for his work in the development of genomic selection, which revolutionized the agricultural and livestock industries.

To become a member of the NAS, one must be nominated by an existing member; there is no application process. A scholar must be recognized as distinguished in his or her area of research, going through a rigorous process in which existing members closely review the nominee's publications and/or scientific data. The NAS judges whether or not the material is impactful and extraordinary enough to the scientific community to consider the prospective nominee an expert in his or her field. The number of new members elected every year is limited to 84 U.S. resident citizens and 21 foreign residents annually, with elections held each April. Currently, the NAS has roughly 2,300 native members and 460 foreign members, each of whom has contributed to the advancement of science.

Nightingale Plan

The Nightingale plan, a model of how health-conscious hospitals should set up their wards, was named after the Englishwoman Florence Nightingale (1820–1910),

who served as a nurse in the Crimean War (1853–1856). Afterward, she founded the first secular school for nursing in the world in London. She is credited with having helped to advance the knowledge of proper hygiene and treatment in hospitals and for setting about the training of professional nurses. News of her work inspired nurses in the American Civil War and the female volunteers of the U.S. Sanitary Commission, who put Nightingale's plans into action in that conflict. American women also used Nightingale's writings as the basis for the professionalization of nursing and the transformation of nursing into a profession for women.

During the early 19th century, germ theory and basic hygienic practices were largely unknown to most physicians. There was understanding that overcrowding in hospitals and other areas could cause illness to spread, but that was seen as a result of impurities in the air, not of viruses or harmful bacteria. Water and food-borne diseases had not yet been fully understood or identified. Even Nightingale did not think that diseases could spread from contact; however, she did see that certain environmental factors could be detrimental to the health of those recovering from wounds and illnesses.

In 19th-century England, there were several breakouts of cholera and other epidemics that occurred in workhouses, boarding institutions, and other establishments that held large numbers of destitute people, including children. One institute in Tooting experienced a severe outbreak of cholera in the year 1849, where a minimum of 200 poor children died. An inquest later revealed that the outbreak had been a result of the children's poor diet and overcrowding. Most shocking for the British population was the high number of deaths caused by infection in the hospital in Scutari—located in what is now Istanbul—during the Crimean War. The barracks lacked nurses, nutritious food, clean water, laundry or spare clothing, a kitchen for proper cooking, and appropriate tools or amenities to take care of the sick and wounded. The reality of the soldiers' pitiful conditions eventually motivated the army to call out for aid. Nightingale and her nurses answered the call.

The Nightingale nurses were not the only ones who worked with the infirm. Long before nurses were professionally trained and disciplined, religious groups such as the Catholic Sisters of Mercy and the Church of England Sisters had reached out to help

with the sickly and dying wherever aid was required. After the Crimean War, Nightingale established a nursing school with the monetary gifts she received.

During the American Civil War, some infirmaries were taken care of by personal friends of Nightingale and other women who had studied her ideas of sanitation and nursing. Dorothea Dix, as the superintendent of army nurses, certainly understood and promoted the Nightingale plan in her crusade to organize nurses and provide soldiers with adequate battlefield health care. Clara Barton, who founded the Red Cross, also knew something of the Nightingale plan, though her work on the battlefield was often in conditions so rough that good hygienic practices were impossible. In the early 1900s, several nations joined in the Red Cross movement, and in 1909, the parties agreed on a resolution that honored Nightingale and her work as the starting point from which the Red Cross's activities had stemmed.

The mid-19th century was marked by humanitarian and architectural concerns in regard to public health centers. Nightingale's work during the Crimean War inspired her to write pieces about improving the structure of hospital wards, including providing enough space in them to prevent impurities from filling up the air. The Nightingale ward plans were long, narrow blocks without high ceilings but with tall windows along both sides of the rooms at regular intervals to allow fresh air to continually move throughout the wards. Between each pair of windows was space for a single bed. While the plans were named after Nightingale, the idea for them was not hers alone. Nonetheless, her writing on nursing and hospital construction played an important role in American women's history.

North, Simeon (1765–1852)

Simeon North was a farmer and gun manufacturer credited with developing a machine that moved factory tool production a step closer to interchangeable parts: the milling machine.

North was born in Berlin, Connecticut, in 1765. He was a farmer from a wealthy family. Adjacent to his farm was a mill on a brook. He bought that property in 1795 so he could manufacture scythes at the mill.

Tool manufacture at the time was done by hand. Each tool was individually crafted, so parts were not identical. A craftsman made each piece and then assembled the tool. North's tools were known for high quality.

He was asked to make pistols, which were more complicated than farm tools. Their parts had to fit precisely, or the guns would not fire. The quality of North's crafted pistols resulted in a U.S. government contract in 1799 for 500 single-shot horse pistols. Horse pistols were flintlock guns that officers fired while riding horseback. North had one year to fill the contract. The 1799 contract was followed by another in 1800 for 1,500 pistols, with two years to deliver the guns. North received government contracts for the next 52 years.

North searched for ways to increase sales volume while maintaining quality. Individually crafted gun parts were not always identical, so a broken part could be impossible to replace, rendering a gun unusable. North and others worked to produce parts that were identical in size and shape so that if a gun part broke, it could be replaced and the gun would function again.

North received a government contract in 1813 to manufacture 20,000 pistols to be delivered in five years. A second factory was built in Middletown, Connecticut, to complete the large order. This contract was the first that stated that North's pistols would have interchangeable parts. The parts would be measured to a standard, uniform size.

A milling machine could produce such parts. North is credited with inventing a milling machine around 1816 that cut metal in a specified pattern or shape with exact dimensions. Parts were then checked with gauges to ensure that each part was identical in size and shape.

North's milling machine parts were the closest to achieving interchangeability at the time, but not 100 percent of the parts were interchangeable. Some still had to be filed down by workers to complete a gun assembly.

North began manufacturing rifles in 1823 and continued to produce quality guns for the rest of his life. He died in 1852. He is remembered as an innovator whose machine advanced the goal of interchangeable parts for many types of other machines.

Omnibus System

"Omnibus" refers to a passenger-carrying vehicle that is pulled by a horse. In the 1800s, omnibus systems were developed throughout Europe and America.

Public transportation vehicles were first introduced by French inventor Blaise Pascal in the 1600s. He proposed the idea of facilities for public transportation in Paris, and it was financed by the local nobility, which issued the construction of carriages that could potentially hold up to eight passengers. In 1662, the carriages became operational and charged a small fare. The idea was popular initially, but people at the time rode them for amusement rather than for practical daily transportation. As a result, the service ceased. Toward the end of the 1700s, cities and roads were developed to a point that allowed for the rise of the omnibus system. In the 18th century, horses and wagons had been the main method of transportation,

pulling small wagons of food and goods over land. Eventually, the idea of public transportation was picked up again in the 19th century.

In 1823, Stanislas Baudry introduced a vehicle that ran from the Nantes Central Square of Nantes to Richebourg for bathing guests; however, he realized that it could be more practical as local transportation. He commissioned an English coach maker named George Shillibeer to design a vehicle that was stable and large enough to carry many passengers. In 1828, the first omnibus service began, running between la Madeleine and la Bastille. The ride took about 15 minutes and cost about 25 centimes. Within six months, about 2.5 million passengers had used the service. The omnibus system would continue to expand throughout Paris, London, and even the United States.

The first omnibus system in the United States began in New York City in 1830. Horse-drawn carriages were then the main method of transportation; John Stephenson built the first horse-drawn railcar in 1832. He became the first president of the New York and Harlem Railroad's Fourth Avenue Line. Over the next 30 years, the omnibus system grew, but the carriers could not accommodate that many passengers, and fares were relatively high. The development of paved roads helped smooth the ride of the omnibus wheels and made trips faster. Horse-drawn streetcars became the main method of transportation in the 1850s. Those who lived in suburbs or residential areas utilized the horsecar system to commute to downtown. The system spread to cities such as San Francisco, California, in the 1860s and Los Angeles and Oakland in the 1880s.

The omnibus went through a number of improvements throughout the years. For many years, the bus remained a single-deck vehicle that seated about two or three people; later, there was a second row that accommodated another two or three people. In 1851, London staged the Great Exhibition, where producers of omnibuses bolted in a plank along the curved roofs of their vehicles to allow more passengers to sit.

Horse cars had some drawbacks. For instance, they did not meet the demand for cheaper and reliable urban transportation. Also, overworked horses could drop dead from exhaustion. Horse feces and urine caused sanitation problems in American cities on a scale now unimaginable. Plus, horses could only work

part of the day, so horses would have to be changed as the hours went by. Last, horses could not pull cars up steep hills, making public transportation a challenge in hilly cities like San Francisco.

The omnibus system led to other innovations in transportation. Tram systems, which consisted of horse-drawn passenger tramways, eventually led to the development of cable cars in the 1880s. These moved along steel rail lines and were eventually powered by electricity and moved continuously. In the 1880s, the Chicago Railway converted to cable cars and eventually to electric trolleys by the 1890s.

For the next 30 years, a variety of transportation sources were available in American cities and towns. Streetcars, horse-drawn carts, and carriages all shared the same roads. There were also elevated tracks, called “els,” that were built about 25 feet above the ground and used mainly by commuters into the city. The late 20th century, however, saw the removal of many city streetcar systems, though some still remain today.

Papermaking Machine

Paper has been around for centuries, and despite today’s technological advancements that have promised paperless offices, paper is still relevant today. But it would not be as available to the public had it not been for many industrial innovations. The papermaking machine had quite a history in Europe before it first made its way to the United States. Thomas Gilpin’s papermaking machine was not only the first in the United States but the first in the world that included the use of a cylindrical mold. It appeared in 1817.

Gilpin and his brother, Joshua, founded Brandywine Paper Mills after producing their first paper in 1787. Its location in Delaware could not have been better, since the required materials were easily obtained nearby or shipped via Brandywine Creek. The supply of fresh water was crucial in the process of papermaking. A year after the brothers manufactured their first paper, they met Nathan Sellers, from whom they bought paper molds.

Joshua visited Europe to further expand his knowledge of the machine-papermaking process. The manager of Brandywine Paper Mills, Lawrence Greatrake, acquired a drawing of the Fourdrinier paper machine done by one of its creators, John Hall. The Fourdrinier machine was one of the two more advanced papermaking machines in Europe. The second machine, which John Dickinson patented in 1809, was based on the use of a cylinder to create a continuous sheet of paper. Though he did not share any documentation of his machine, Dickinson gave Greatrake permission to draw it, because he was confident that his work could not be duplicated, especially since most of the mechanical details were unseen.

However, Greatrake succeeded in collecting what Gilpin needed to incorporate in his new papermaking machine, which greatly took after both the Fourdrinier and Dickinson machines. Gilpin earned his patent in 1817, and the machines that influenced his model would not be introduced to the United States until at least a decade later.

Pencil Eraser

Modern pencils come topped with erasers and are one of the most familiar objects in American daily life. Hymen Lipman (1817–1893) patented the first pencil-and-eraser combination in 1858. Historians believe that the first wood-encased pencils date to about the 1500s, while erasers were developed by Edward Nairne in 1770. However, Lipman was the first person to think of combining both objects into one instrument, patenting a wood-encased pencil that contained lead on one end and an eraser on the other in 1858. In 1862, he sold the rights to his patent to Joseph Reckendorfer for \$100,000.

The Supreme Court of the United States invalidated the patent in 1875, however, concluding that Lipman had only put two existing objects together rather than invented something new. The ruling meant that pencil manufacturers were free to modify Lipman's initial design. The Faber Pencil Company soon developed a pencil with an eraser attached to the top—the design widely used today.

Pepper (and Salt) Shaker

The two most common ingredients used to season any dish are salt and pepper. Many years ago, salt and pepper had a value on the same level as currency in some parts of the world.

John Landis Mason, who was also the creator of the mason jar, invented the salt shaker in 1858. His design included the application of a screw top lid. Though his idea was innovative, in addition to its

perforated cap design, it did not achieve much success or attention until the 1920s. The design of the product was not the issue, but rather the clumping quality of the salt, which prevented it from passing through the holes. Many others followed Mason with their designs, including one for a single shaker that contained both salt and pepper and another for two similar-looking shakers but one with a special marking for the pepper.

Perkins, Jacob (1766–1849)

Jacob Perkins was a mechanical engineer, inventor, and physicist who was known for a variety of useful inventions, most significantly the first ice-making refrigerator. Perkins was born in Newburyport, Massachusetts, on July 9, 1766. He left school at 12 years old and became an apprentice to a goldsmith named Davis. After the goldsmith died, Perkins continued manufacturing gold beads, and he perfected a method for creating gold-plated shoe buckles at 15 years of age. When he was 21, he became known for making dies for striking copper coins.

In 1790, he invented a machine for cutting nails with implanted heads. This invention greatly simplified the nail manufacturing process. He operated a nail-making business, but a lawsuit forced him to shut it down. Due to this setback, Perkins's next plan was to improve the way that banknotes were engraved by using steel plates instead of copper ones—a process that made counterfeiting more difficult. He traveled to England in 1818 to supply local banks with his plates in hopes of finding investors to fund his engraving technology. He established a London plate-manufacturing business as a result of his efforts. At the same time, Perkins worked on steam engines and technology for steam guns.

Jacob Perkins invented an early refrigerator, as well as innovating in gun and steam technology. He also improved the engraving process for bank notes by using steel plates, rather than copper. (Science & Society Picture Library/Getty Images)

In 1805, Oliver Evans was the first person to design an ice-making machine, but he never finished his project. In 1834, Perkins modified Evans's design and finished building the first ice machine known as the refrigerator. It used closed-cycle vapor compression. His work was inspired by the refrigeration principles developed by Benjamin Franklin and others.

Perkins's refrigeration machine was not safe for domestic use, however, because it relied on dangerous substances like ammonia and ether in its cooling process. These gases were used to absorb heat and lower the temperatures of nearby objects. Perkins effected this by using a compressor to exert pressure on the dangerous gases to convert them to liquid that then moved through the machine's coils to absorb heat. As the pressurized liquids absorbed heat, they returned to their gaseous form before returning to the compressor for repeated use.

In November 11, 1790, Hannah Greenleaf of Newbury married Perkins; they had nine children.

Their second son, Angier March Perkins, was also an engineer. Angier Perkins worked for most of his career in the United Kingdom and was eager in inventing new technologies for central heating. He partnered with his father and eventually took over the family business. Loftus Perkins, a grandson, also became an engineer, and he devoted his time to improving refrigeration and heating, as well as further developing the steam engine. Jacob Perkins retired in 1843 and died in London, England, on July 30, 1849. He is buried in Kensal Green Cemetery, London.

Platform Scale

The platform scale, which weighs large or heavy objects by use of an automatic system of levers and adjustable weights, was invented by Thaddeus Fairbanks in 1830. In 1824, he started E & T Fairbanks, a company with his brother Erastus. Their association with a failing hemp dressing business shined a light on another issue: they had noted that the existing method of weighing things was flawed. It required a series of steps, including suspending the material to be weighed, which was difficult with larger and heavier objects.

After many iterations, Thaddeus's invention was finally built in 1830. His apparatus did not require unloading or suspension; only the rolling of a wagon that the material was placed in onto the scale. He was awarded a patent for the platform scale in June 21, 1831. He and his brother would later receive others

under differing categories, such as “weighing heavy bodies.”

Polished Steel Plow

A blacksmith by trade but a genius by reputation, John Deere will be remembered for inventing the first successful polished steel plow in 1837. It revolutionized farming by breaking up the thick, clay-like soil and root mats created by the indigenous prairie grasses of the American Midwest. This allowed the region to earn the title, “the nation’s breadbasket.” The plow led to the establishment of Deere & Company, one of the largest agricultural and construction equipment manufacturers in the world.

While the new plow may have been John Deere’s idea, the inspiration belonged in part to his father, William, a merchant tailor, who polished his sewing needles to pierce fabric smoothly. When John Deere left his home in Vermont in 1836 to seek his fortune in Illinois, he took his blacksmithing skills with him, and also the memory of his father and his shiny needles.

Farming in the Midwest was different from anything Deere and other East Coast transplants had ever experienced. Unlike the sandy New England soil, the Midwest’s was dark, moist, and sticky, and it clung to cast-iron plows, adding hours to the planting process. Deere, who had a blacksmith business in Grand Detour, Illinois, was convinced that a plow that was highly polished and properly shaped could scour itself as it cut furrows. In 1837, he created such a plow using a broken saw blade. That first plow led to another and another, and by 1841, he was building 100 per year and realized that he would need the backing of a partner to expand the operation.

Leonard Andrus joined the effort, and together they produced plows in Grand Detour until 1848,

when they parted company and Deere moved the business to Moline, Illinois. The larger city, perched on the Mississippi River, was also a rail hub, which meant that the raw materials needed to build the plows could be acquired both quickly and cheaply. The new location also meant a new factory, which was built with new partners: Robert Tate and John Gould. A year after arriving in Moline, the company was turning out 200 plows a month. Tate’s and Gould’s positions were bought out in 1853, and Charles Deere, John’s son, came into the business. Over the next five years, wagons and corn planters were added to the inventory, and that diversification may have played a role in seeing the company through the financial panic that swept the United States in 1858. It did require John Deere to sell a controlling interest in the company to his son, however, who then managed the daily operations. But John Deere remained active in the company, serving as president until his death in 1886.

Today, the Deere Corporation’s distinctive green-and-yellow color scheme adorns thousands of tractors, combines, and construction machines around the world.

Printing

You wouldn’t be reading this book if printing hadn’t been invented. From woodblock to moveable type to digital printers, printing technology makes life a joy and a job. Printing allows people to communicate. It lets us remember what we’ve heard, said, or seen. History can be written down so that people know what happened and who was there. Information can be shared and business transactions logged; so can details, important and not so important. Printing has improved how we communicate.

Printing has changed over time, although all printing consists of something to write with, an ink, and something to write on. Before the Common Era, Egyptians were writing on papyrus. Fiber taken from the papyrus plant was made into thin sheets that were overlapped and then pressed so they would stick together to form a single sheet. Scrolls could be made from sheets into different lengths as needed. Brushes made from reeds were used to write on the papyrus. Ink was made by mixing carbon black, gum arabic, and water. Papyrus is still in existence today; many ancient examples show drawings of people, their way of life, and events long gone by.

Since papyrus was not widely available and somewhat expensive, people looked for other materials to write on. In countries around the Mediterranean long ago, untanned and tanned animal skins were used to produce parchment. The skin was scraped, soaked, cleaned, stretched, and dried. The resulting writing surface was smooth to write on. Unlike dried animal skin treated to become leather, parchment absorbs moisture and is smooth. Hollow reeds with one end cut to a point were used to write with. Water mixed with gum arabic and a pigment made up the ink.

Woodblocks were used in China almost 2,000 years ago to print images and words onto textiles. Printing was also done on silk, bones, and bamboo. By the seventh century, printing was done on paper, although not of the best quality. Some paper was made from linen or cotton; because it was soft, it was difficult to use and preserve. But over time, paper quality was improved with the addition of wood pulp to the cotton. China continued to improve the quality of paper. The Chinese used ink made from black pigment from pine-wood combined with animal glue and something to maintain consistency, such as egg white or camphor.

Block printing was used in the Middle East for prayer books in the ninth century. Small woodcut cards were produced in Europe in the 14th century, especially of religious images. These were printed much like stamps, just as we could do today. Any text on the card was added by hand, so making these images was a slow process.

The invention of movable type created a faster means of printing books. Johann Gutenberg (1398–1468) revolutionized the printing process with the

invention of movable type. Essentially, instead of using a single large stamp for printing the whole image of a page, he designed a series of small stamps, each representing a single letter of the alphabet or number, to print the text of a book. Each stamp had to be exactly the same size and shape so that they could easily be removed if needed without disrupting the rest of the page to be printed. These individual stamps would be assembled line by line within a frame to print a page of text. Mistakes could be corrected by replacing the individual stamp in error—but proofreading was essential. When the page was perfect, one copy or multiple copies could be produced. Afterward, the letters would be disassembled and the next page of text could be created, reusing the same individual letter stamps.

The individual letter stamps had to be sturdy to be used in printing after printing; they were made of metal—usually tin or lead. When text was printed, some areas were left blank so that images or decorations could be added by hand.

Gutenberg's machine pressed letters down uniformly and with more force than a person could press down a stamp, created a more uniform print overall. His was not an easy machine to build. Developing and improving it took him 20 years.

The quality of the ink used with these stamps was important. Water-based ink did not work well with the metal stamps. When they were pressed against the paper, the ink had to not run or smear, and it had to be the right consistency to produce a readable letter that didn't blur on the paper and distort a word. Gutenberg used an oil-based ink with carbon, copper, lead, and other pigments for color.

His faster printing process would have been of no use, however, with nothing to print on. But cheap paper was available in quantity by the time Gutenberg's press was ready to begin.

Gutenberg began printing Bibles in 1454. The text was two columns per page, with 42 lines on each page, and it was in Latin. Between 200 and 300 Bibles were produced, with least 30 printed on vellum (calf skin) and the rest on paper. Each had 1,282 pages. Gutenberg had produced the first printed book.

Unfortunately, Gutenberg went into debt to produce his invention and lost all his tools, the printing

presses, and his shop to those he owed money to. They published the Gutenberg Bible while he died in debt.

But Gutenberg's invention had changed the production of books forever. Classical manuscripts were being mass-produced by the early 16th century, and the price of books decreased while the number of books increased.

Every European country had a printing press within 15 years of Gutenberg's invention. Martin Luther and others used it to print pamphlets to distribute to followers. Ideas could be disseminated to more people because of the printing press, and more books were printed in the next 50 years than had ever been printed before. The first newspaper opened in Germany in 1609.

Printers began making improvements to the printing press to make it sturdier. Iron and brass replaced wood. Levers were introduced to replace the screw mechanism that had been used to press the letter stamps onto the paper. The lever allowed more uniform tightening and more uniform-looking print. But the printing press was still a labor-intensive machine.

William Nicholson patented "A Machine or Instrument on a New Construction for the Purpose of Printing on Paper, Linen, Cotton, Woolen and other Articles in a more Neat, Cheap and Accurate Manner than is effect by the Machines now in use" in 1790. His machine had multiple rotating cylinders. On was a cylinder of rotating letters to be printed, another held the sheet of paper to be printed on, and another spread ink on the form. However, the intricate machine was never built due to lack of money.

Soon, though, printing became a business that many could enter, including Benjamin Franklin, who made his fortune as a printer before moving into politics during and after the American Revolution.

Inventors continued to make improvements and changes to the printing press. Friedrich Koenig invented the double-sided press in 1814. Around 1843, Richard M. Hoe invented and built the first practical rotary press to print on long rolls of continuous paper. The design was updated and improved by William Bullock, who patented a steam-powered press fed by rolls of paper in 1863. His press could print 12,000 newspapers an hour.

Typewriters were developed in the 1870s, and within 15 years were used in many business offices. The machine used moveable-type letters, symbols, and numbers. Printing could now be done on an individual basis as needed.

Printing has become even more technical today. Inkjet printers were invented in the mid-20th century. Inkjets rely on small droplets of ink sprayed on paper to recreate digital images. Laser printers use digital printing as well. A laser scans over a drum to produce the image to be printed using powdered ink.

Handwritten text has largely been replaced by mechanical printing. Labor-intensive printers have been replaced by machines. Computers with keyboards have replaced typewriters. Printing still requires something to write with and the something to write on—at least for now.

Printing Telegraph

The printing telegraph was developed as an alternative to the Morse telegraph with the goal to eliminate the coding and decoding of each symbol as a set of dots and dashes. Samuel Morse's method required trained personnel on both receiving and transmitting ends, which severely limited its speed. As an alternative, Alfred Vail, Morse's partner, proposed in 1837 that the printing head should utilize a wheel with all 24 letters of the alphabet. The wheel would then be moved by a spring mechanism similar to the one used in clocks,

and an electromagnetic key would stop the wheel at a particular position according to the received letter, requiring precise synchronization between the sending and receiving parts. According to an agreement between Vail and Morse, Vail abandoned his idea and gave all credit to Morse.

The first practical printing telegraph was invented by Royal E. House, who obtained a patent for it in November 1848. However, in 1847, in a letter to the *Philadelphia Ledger*, Samuel Morse claimed that he already invented a telegraph capable of printing letters of the alphabet. The investigations of and arguments over the originality of House's design in comparison to Morse's patent from 1837 took almost two years, and in the end, House's telegraph was classified as a "signal and printing telegraph," while Morse's was a "writing telegraph." As a result, the effective date for House's patent was changed to April 18, 1846.

As proposed, the House printing telegraph consisted of both a transmitter, called a composer machine, and a receiver/printer. The composer machine and printer were moved by a crank connected to a balance wheel to ensure smooth motion. In a subsequent version, a cylinder with pressurized air was used to move the parts. On the composer side, the printing telegraph used a keyboard similar to a piano keyboard with 28 keys. Under the keys was a cylinder with spiral-mounted pins. When a key was pressed, the cylinder and attached tooth wheel would stop at the position corresponding to a particular letter, punctuation mark, or space. When the cylinder was moved from one letter to another, a sequence of contacts and interruptions was given so that the wheel on the receiving part was in the exact same position as the one on the sender's side. When the wheel stopped on the receiver's side, the corresponding letter was marked on paper.

The House telegraph was first used successfully in 1849 between New York and Philadelphia. Although it was a much more complex instrument than the Morse telegraph, it offered greater flexibility and a notably higher speed. Unfortunately, it was also expensive, very complex, difficult to manufacture, and was not designed for (and performed poorly on) long lines. Despite the fact that a significant number of House systems were installed on the East Coast of the United

States between 1849 and 1860, the apparatus was gradually replaced by other machines—in many cases by David Hughes's telegraph, which was invented in 1855. In 1857, the newly formed American Telegraph Company purchased Hughes's telegraph and gave it to George M. Phelps for improvement. Phelps had already opened a shop in Troy, New York, called House's Printing Telegraph Instrument Manufacturer, and in 1856, the American Telegraph Company made Phelps superintendent for production of the recently purchased Hughes telegraph. In 1866, the Western Union Company, which manufactured House telegraphs, purchased the American Telegraph Company and made Phelps responsible for the mechanical department—first in Troy, then Williamsburg, and ultimately New York City. Using his experience with both the House and Hughes printing telegraph systems, Phelps developed an electromotor printing telegraph capable of operating over long lines.

Developments and improvements of the printing telegraph continued over the next few decades, including the Essick page-printing telegraph, which was introduced in 1894 by the Union Telegraph and News Company of New York as a system designed to work private lines and railway service. The Essick system was advertised as capable of being attached to any telegraph line while using less power compared to the Morse telegraph. In addition, the Essick telegraph could work on lines of any length and was much smaller in size.

Pullman, George Mortimer (1831–1897)

George Pullman was a pioneering businessman in the 19th century. He is best known for the development of the Pullman Sleeping Car, an innovation that offered comparative luxury for nation's long-distance rail travelers.

George Pullman was born on March 3, 1831, in Brockton, New York, the third of nine children born to James Lewis Pullman and the former Emily Caroline Blunt. Pullman had little formal education, having quit school after the fourth grade to work in a local general store owned by his mother's uncle. In 1848, Pullman moved to Albion, New York, joining his father, who had started a business moving buildings out of the way of the advancing Erie Canal. After his father died in 1853, George took over the business. His big break soon came when, working on the setup of Chicago's new sewage system, he was able to lift the buildings so efficiently that businesses were able to operate uninterrupted. With the resulting income, in partnership with friend and state senator Benjamin Field, he started a sleeper car company in 1857.

Pullman's Palace Car, a luxury version of an idea dating back to the 1830s, represented a radical departure in comfort and attractiveness. While previously the goal had been to minimize discomfort, Pullman sought to entice people to experience the trip in style. Initial public response was overwhelmingly positive, but the company's future was secured after Pullman offered the use of a car to Mrs. Mary Lincoln when she accompanied her slain husband's body back to Springfield, Illinois, for burial.

Leasing the cars to the railroads rather than selling them, the company prospered, with approximately 2,000 cars leased out and a net worth estimated at about \$62 million at its peak. In 1867, after Field ended their partnership, Pullman formed the Pullman Palace Sleeping Car Company, of which he was president and general manager. With the new company, Pullman sought to consolidate operations and get an ever greater control of all aspects of his business. In 1880, Pullman bought a 4,000-acre tract near Lake Calumet just south of Chicago. There he built a new

factory and established a community consisting of 1,300 housing units as well as shopping areas, churches, parks, a hotel, a library, and a man-made lake, all of which Pullman controlled.

The dangers of the arrangement became clear when in response to the recession of 1893, Pullman cut workers' wages but refused to lower any costs related to living in the town. The predictably disgruntled workforce resorted to a massive strike, which, supported by the American Railway Union, became a national event and was settled only when President Grover Cleveland dispatched troops to end it. A national commission established to investigate the landmark strike laid much of the blame at the feet of Pullman and the paternalism involved in his operation of a town that the report called "un-American." Indeed, following up, in 1898, the Illinois Supreme Court forced the company to divest its ownership interest in the town, which was later annexed by Chicago.

By that time, George Pullman had died of a heart attack on October 19, 1897. After a private funeral, he was buried in a specially secured structure in Chicago's Graceland Cemetery.

Railroad T-Rail and Tie

Many of the basic design features of modern railroad track were first used in 1831 on the Camden and Amboy Railroad, a short line in New Jersey. The track

design, including an all-iron rail with a T-shaped profile, was designed by Robert L. Stevens (1787–1856), the president and chief engineer of the line.

Most of the earliest railroads in the United States had been built using strap rail, which consisted of a solid wooden plank laid across the ties (the ties—called “sleepers” in Great Britain—are the crosspieces between the rails, which provide a foundation for the track and aid in keeping the rails in gauge). The wooden plank was topped with a thin strap of iron, and the wheels of the locomotives and cars rode on this iron strap. The iron strap was usually about five-eighths of an inch thick, about two and a half inches wide, and made in strips 18 feet long. This rail was suitable only for lightweight equipment carrying relatively small loads, but most of the locomotives and cars in use were much smaller and lighter than what would become standard a few years later.

There were problems with strap rail, even with the lightweight equipment in use. The thin strip of iron tended to wear quickly. A somewhat rare but dangerous problem was what were called “snakeheads”—the iron strap would sometimes break and curl back like a snake rearing to strike. This bent piece of rail could break through the bottom of railcars and do serious damage to cargo or harm to passengers. Despite these problems, about 3,000 miles of strap rail was laid on the earliest U.S. railroads.

Robert Stevens considered himself primarily a naval architect, and he and his father, John Stevens, were heavily involved in the development of steamboats in the United States. The Stevens family was the major backer of the Camden and Amboy Railroad, which was incorporated in 1830. While Robert was made president and chief engineer of the railroad, his brother Edwin A. Stevens, was also an officer of the company.

When the railroad’s executives decided not to use strap rail, they found that no foundries in the United States could make the type of rail that they hoped to use. Robert was sent to England to buy rail, and while on the journey, he carved several different wooden patterns of the type of rail he envisioned, finally settling on the T-rail design. Stevens had trouble finding a foundry in Great Britain willing to make his rail, but it was finally produced by an ironworks in Dowlais,

Wales, owned by Sir John Guest, a member of Parliament. The first shipment of rails arrived in Philadelphia in May 1831.

Stevens also ordered six-inch spikes with a hooked head; this type of spike has become known as a “dog spike,” and its use on the Camden and Amboy marked its introduction to the United States. The Camden and Amboy Railroad first intended to lay its rail on stone ties, but when the supply of these ties ran short, it turned to wooden ties. The system of wooden ties lying in a bed of gravel ballast with the T-rails secured to the tie with hook-headed spikes was all part of Stevens’s innovative design on his railroad.

Railroad builders consider the design of the T-rail to be very practical, and though it has been slightly modified over the years, it has never been surpassed. The head of the rail has a large mass to support the weight of railroad cars and locomotives and can take a substantial amount of wear before needing replacement. The vertical portion of the rail, called the “stem” or “web,” connects the head to the wide, flat base that provides stability. T-rail has been used by railroads throughout the world. An English designer, Charles B. Vignoles, developed a similar design in 1836, and this type of rail is often referred to as “Vignoles rail” in Europe.

Railroads

Railroads revolutionized the transport of goods across the United States. In the 19th century, as more and more people populated the West, railroads became the reliable method to travel back and forth. Railroads

also allowed farmers to get their crops to market relatively quickly and inexpensively. Railroads are one of the landmark developments of the 19th-century Industrial Revolution, both as products of other technological revolutions like steam power and steel production and as a driver of westward expansion, industrialization, and urbanization.

The British pioneered rail lines and steam power in the first decades of the 19th century. A number of Americans investigated the British rail system and worked to bring the innovation to the United States. The oldest railroad in the United States is the Baltimore and Ohio (B & O) Railroad, completed on February 28, 1827. Baltimore proved more eager than other major American cities in part because the city had no canal. A railway based in Charleston, South Carolina, soon followed. The South Carolina Canal and Railroad Company featured the country's first commercially available steam locomotive, the *Best Friend of Charleston*.

Railroads played a crucial role in the American Civil War, so much so that historians generally cite them as one of the top reasons that the Union won the war. First, Northern states had industrialized and not only had a considerable number of railroad companies and thousands of miles of rails, but they had the means to produce additional rails, locomotives, and railcars. Southern states, particularly those that became part of the Confederate States of America, tended to be agricultural rather than industrial, a by-product of the region's commitment to black slavery. When the war began, the Union could move troops and goods much more quickly and efficiently than could the Confederacy. Also, as the Union Army encroached on an area, it would destroy Southern rail lines, crippling the Confederacy. Because the war was fought mainly in Confederate territory, the Union's ability to destroy rail lines became one of the crucial factors in the Union's ultimate victory.

The Transcontinental Railroad system, built to connect the eastern United States with the West, joined the Union Pacific Railroad and Central Pacific Railroad. The two companies began at separate locations and joined up between them. One company went west from Omaha, Nebraska, while the other lay tracks from Sacramento, California. The companies eventually met

at Promontory, Utah, on the date of completion in 1869, marking the first time that a railroad connected the East of the United States to the West.

The first transcontinental railroad had legal troubles, and both companies found ways to benefit monetarily (each company received 12,800 acres of land and \$48,000 in bonds from the government for each mile of track it set) while competing to be the first to get farthest across the nation. At the helms of each company were people who felt that being the first to revolutionize the industry would serve them well in the future. At the Sacramento starting point were four like-minded and creative businessmen—Charles Crocker, Leland Stanford, Collis Huntington, and Mark Hopkins—who were ready to make corrupt choices to exploit loopholes and make the most money possible by milking the government of resources. At the Omaha starting point was an educated man named Dr. Thomas Durant, who had received full authority over the project illegally. By doing this, he could guarantee profits.

As the two companies worked to quickly lay down tracks and rake in profits, each had troubles. The Union Pacific Railroad, while moving westward, was faced with attacks from the Native Americans who were losing land to the railroad and fearful of the progress that the white man was making. As people moved westward, they created settlements known as part of the “Wild West.” The Central Pacific Railroad, with Charles Crocker in charge of construction, began to hire Chinese workers in 1865 who had already been on the West Coast, having arrived in time for the California Gold Rush. The Chinese workers were tireless laborers who would do anything to make their way in the United States and assimilate.

The Union Pacific Railroad began to pull away from the Central Pacific Railroad in terms of ground covered by railroad tracks in the summer of 1867. In the race for each to get ahead of the other company, the final stretch became a gruesome one, so the government stepped in with Ulysses S. Grant, who was president at the time, and withheld funding in early 1869 until the companies established decorum and a meeting point at Promontory Summit. They would eventually complete the railroad on May 10, 1869, by driving a final spike into the ground.

In the late 19th century, railroad companies consolidated to such an extent that the U.S. Congress responded with anti-monopoly legislation. Large railway companies like the Great Northern or the Southern Pacific created immense problems for farmers, who were forced to rely on a single company to get their goods to market. The so-called robber barons of the age—men like Cornelius Vanderbilt, Jay Gould, Collis Huntington, and Leland Stanford—made immense sums of money while pauperizing farmers, who were forced to pay high shipping rates or lose their crops. Railroad barons also benefited from federal and state government policies friendly to large corporations.

In the 20th century, as other transportation methods began to take over personal transportation (particularly automobiles), the railroad industry began to focus on commercial markets that moved goods from ports into the rest of the country. Also, as automakers tackled energy-efficient technology, so too did railroad companies, introducing diesel-electric locomotives to the rails. Finding an effective way to use the transport method while also saving money worked out well for the suppliers of goods and the people operating the railroad systems. Farmers and corporations would pay less for shipping costs, and fuel for the

railroad systems would make less of a hole in the operators' pockets.

Today, the railroad system in the United States is primarily a means of transporting goods from the ports and across the country, or from manufacturer warehouse points inland. In addition to shipping goods, railroads offer a means of cost-effective and scenic vacation or business travel.

Primary Document: Pacific Railway Act (1862)

Enacted in July 1862 during the Civil War, the Pacific Railway Act allotted federal funds and land for the construction of a transcontinental railway. Such legislation had been strongly opposed by the Southern states prior to their secession.

CHAP. CXX.—An Act to aid in the Construction of a Railroad and Telegraph Line from the Missouri River to the Pacific Ocean, and to secure to the Government the Use of the same for Postal, Military, and Other Purposes.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That Walter S. Burgess, William P. Blodget, Benjamin H. Cheever, Charles Fosdick Fletcher, of Rhode Island; Augustus Brewster, Henry

P. Haven, Cornelius S. Bushnell, Henry Hammond, of Connecticut; Isaac Sherman, Dean Richmond, Royal Phelps, William H. Ferry, Henry A. Paddock, Lewis J. Stancliff, Charles A. Secor, Samuel R. Campbell, Alfred E. Tilton, John Anderson, Azariah Boody, John S. Kennedy, H. Carver, Joseph Field, Benjamin F. Camp, Orville W. Childs, Alexander J. Bergen, Ben. Holliday, D. N. Barney, S. De Witt Bloodgood, William H. Grant, Thomas W. Olcott, Samuel B. Ruggles, James B. Wilson, of New York; Ephraim Marsh, Charles M. Harker, of New Jersey; John Edgar Thompson, Benjamin Haywood, Joseph H. Scranton, Joseph Harrison, George W. Cass, John H. Bryant, Daniel J. Morell, Thomas M. Howe, William F. Johnson, Robert Finney, John A. Green, E. R. Myre, Charles F. Wells, junior, of Pennsylvania; Noah L. Wilson,

Amasa Stone, William H. Clement, S. S. L'Hommedieu, John Brough, William Dennison, Jacob Blickinsderfer, of Ohio; William M. McPherson, R. W. Wells, Willard P. Hall, Armstrong Beatty, John Corby, of Missouri; S. J. Hensley, Peter Donahue, C. P. Huntington, T. D. Judah, James Bailey, James T. Ryan, Charles Hosmer, Charles Marsh, D. O. Mills, Samuel Bell, Louis McLalle, George W. Mowe, Charles McLaughlin, Timothy Dame, John R. Robinson, of California; John Atchison and John D. Winters, of the Territory of Nevada; John D. Campbell, R. N. Rice, Charles A. Trowbridge, and Ransom Gardner, Charles W. Penny, Charles T. Gorham, William McConnell, of Michigan; William F. Coolbaugh, Lucius H. Langworthy, Hugh T. Reid, Hoyt Sherman, Lyman Cook, Samuel R. Curtis, Lewis A. Thomas, Platt Smith, of Iowa; William B. Ogden, Charles G. Hammond, Henry Farnum, Amos C. Babcock, W. Seldon Gale, Nehemiah Bushnell and Lorenzo Bull, of Illinois; William H. Swift, Samuel T. Dana, John Bertram, Franklin S. Stevens, Edward R. Tinker, of Massachusetts; Franklin Gorin, Laban J. Bradford, and John T. Levis, of Kentucky; James Dunning, John M. Wood, Edwin Noyes, Joseph Eaton, of Maine; Henry H. Baxter, George W. Collamer, Henry Keyes, Thomas H. Canfield, of Vermont; William S. Ladd, A. M. Berry, Benjamin F. Harding, of Oregon; William Bunn, junior, John Catlin, Levi Sterling, John Thompson, Elihu L. Phillips, Walter D. McIndoe, T. B. Stoddard, E. H. Brodhead, A. H. Virgin, of Wisconsin; Charles Paine, Thomas A. Morris, David C. Branham, Samuel Hanna, Jonas Votaw, Jesse L. Villiams, Isaac C. Elston, of Indiana; Thomas Swan, Chauncey Brooks, Edward Wilkins, of Maryland; Francis R. E. Cornell, David Blakely, A. D. Seward, Henry A. Swift, Dwight Woodbury, John McKusick, John R. Jones, of Minnesota; Joseph A. Gilmore, Charles W. Woodman, of New Hampshire; W. H. Grimes, J. C. Stone, Chester Thomas, John Kerr, Werter R. Davis, Luther C. Challiss, Josiah Miller, of Kansas; Gilbert C. Monell and Augustus Kountz, T. M. Marquette, William H. Taylor, Alyin Saunders, of Nebraska; John Evans, of Colorado; together with commissioners to be appointed by the Secretary of the Interior, and all persons who shall or may be associated with them, and their successors, are hereby created and erected into a body corporate and politic in deed and in law,

by the name, style, and title of "The Union Pacific Railroad Company;" and by that name shall have perpetual succession, and shall be able to sue and to be sued, plead and be impleaded, defend and be defended, in all courts of law and equity within the United States, and may make and have a common seal; and the said corporation is hereby authorized and empowered to layout, locate, construct, furnish, maintain, and enjoy a continuous railroad and telegraph, with the appurtenances, from a point on the one hundredth meridian of longitude west from Greenwich, between the south margin of the valley of the Republican River and the north margin of the valley of the Platte River, in the Territory of Nebraska, to the western boundary of Nevada Territory, upon the route and terms hereinafter provided, and is hereby vested with all the powers, privileges, and immunities necessary to carry into effect the purposes of this act as herein set forth. The capital stock of said company shall consist of one hundred thousand shares of one thousand dollars each, which shall be subscribed for and held in not more than two hundred shares by any one person, and shall be transferable in such manner as the by-laws of said corporation shall provide. The persons hereinbefore named, together with those to be appointed by the Secretary of the Interior, are hereby constituted and appointed commissioners, and such body shall be called the Board of Commissioners of the Union Pacific Railroad and Telegraph Company, and twenty-five shall constitute a quorum for the transaction of business. The first meeting of said board shall be held at Chicago at such time as the commissioners from Illinois herein named shall appoint, not more than three nor less than one month after the passage of this act, notice of which shall be given by them to the other commissioners by depositing a call thereof in the post office at Chicago, post paid, to their address at least forty days before said meeting, and also by publishing said notice in one daily newspaper in each of the cities of Chicago and Saint Louis. Said board shall organize by the choice from its number of a president, secretary, and treasurer, and they shall require from said treasurer such bonds as may be deemed proper, and may from time to time increase the amount thereof as they may deem proper. It shall be the duty of said board of commissioners to open

books, or cause books to be opened, at such times and in such principal cities in the United States as they or a quorum of them shall determine, to receive subscriptions to the capital stock of said corporation, and a cash payment of ten per centum on all subscriptions, and to receipt therefor. So soon as two thousand shares shall be in good faith subscribed for, and ten dollars per share actually paid into the treasury of the company, the said president and secretary of said board of commissioners shall appoint a time and place for the first meeting of the subscribers to the stock of said company, and shall give notice thereof in at least one newspaper in each State in which subscription books have been opened at least thirty days previous to the day of meeting, and such subscribers as shall attend the meeting so called, either in person or by proxy, shall then and there elect by ballot not less than thirteen directors for said corporation; and in such election each share of said capital shall entitle the owner thereof to one vote. The president and secretary of the board of commissioners shall act as inspectors of said election, and shall certify under their hands the names of the directors elected at said meeting; and the said commissioners, treasurer, and secretary shall then deliver over to said directors all the properties, subscription books and other books in their possession, and thereupon the duties of said commissioners, and the officers previously appointed by them shall cease and determine forever, and thereafter the stockholders shall constitute said body politic and corporate. At the time of the first and each triennial election of directors by the stockholders two additional directors shall be appointed by the President of the United States, who shall act with the body of directors, and to be denominated directors on the part of the government; any vacancy happening in the government directors at any time may be filled by the President of the United States. The directors to be appointed by the President shall not be stockholders in the Union Pacific Railroad Company. The directors so chosen shall, as soon as may be after their election, elect from their own number a president and vice-president, and shall also elect a treasurer and secretary. No person shall be a director in said company unless he shall be a bona fide owner of at least five shares of stock in the said company, except the two directors

to be appointed by the President as aforesaid. Said company, at any regular meeting of the stockholders called for that purpose, shall have power to make by-laws, rules, and regulations as they shall deem needful and proper, touching the disposition of the stock, property, estate, and effects of the company, not inconsistent herewith, the transfer of shares, the term of office, duties, and conduct of their officers and servants, and all matters whatsoever which may appertain to the concerns of said company; and the said board of directors shall have power to appoint such engineers, agents, and subordinates as may from time to time be necessary to carry into effect the object of this act, and to do all acts and things touching the location and construction of said road and telegraph. Said directors may require payment of subscriptions to the capital stock, after due notice, at such times and in such proportions as they shall deem necessary to complete the railroad and telegraph within the time in this act prescribed. Said president, vice-president, and directors shall hold their office for three years, and until their successors are duly elected and qualified, or for such less time as the by-laws of the corporation may prescribe; and a majority of said directors shall constitute a quorum for the transaction of business. The secretary and treasurer shall give such bonds, with such security, as the said board shall from time to time require, and shall hold their offices at the will and pleasure of the directors. Annual meetings of the stockholders of the said corporation, for the choice of officers (when they are to be chosen) and for the transaction of annual business, shall be holden at such time and place and upon such notice as may be prescribed in the by-laws.

SEC. 2. And be it further enacted, That the right of way through the public lands be, and the same is hereby, granted to said company for the construction of said railroad and telegraph line; and the right, power, and authority is hereby given to said company to take from the public lands adjacent to the line of said road, earth, stone, timber, and other materials for the construction thereof; said right of way is granted to said railroad to the extent of two hundred feet in width on each side of said railroad where it may pass over the public lands, including all

necessary grounds for stations, buildings, workshops, and depots, machine shops, switches, side tracks, turntables, and, water stations. The United States shall extinguish as rapidly as may be the Indian titles to all lands falling under the operation of this act and required for the said right of way and; grants herein-after made.

SEC 3. And be it further enacted, That there be, and is hereby, granted to the said company, for the purpose of aiding in the construction, of said railroad and telegraph line, and to secure the safe and speedy transportation of the mails, troops, munitions of war, and public stores thereon, every alternate section of public land, designated by odd numbers, to the amount of five alternate sections per mile on each side of said railroad, on the line thereof, and within the limits often miles on each side of said road, not sold, reserved, or otherwise disposed of by the United States, and to which a preemption or homestead claim may not have attached, at the time the line of said road is definitely fixed: Provided, That all mineral lands shall be excepted from the operation of this act; but where the same shall contain timber, the timber thereon is hereby granted to said company. And all such lands, so granted by this section, which shall not be sold or disposed of by said company within three years after the entire road shall have been completed, shall be subject to settlement and preemption, like other lands, at a price not exceeding one dollar and twenty-five cents per acre, to be paid to said company.

SEC. 4. And be it further enacted, That whenever said company shall have completed forty consecutive

miles of any portion of said railroad and telegraph line, ready for the service contemplated by this act, and supplied with all necessary drains, culverts, viaducts, crossings, sidings, bridges, turnouts, watering places, depots, equipments, furniture, and all other appurtenances of a first class railroad, the rails and all the other iron used in the construction and equipment of said road to be American manufacture of the best quality, the President of the United States shall appoint three commissioners to examine the same and report to him in relation thereto; and if it shall appear to him that forty consecutive miles of said railroad and telegraph line have been completed and equipped in all respects as required by this act, then, upon certificate of said commissioners to that effect, patents shall issue conveying the right and title to said lands to said company, on each side of the road as far as the same is completed, to the amount aforesaid; and patents shall in like manner issue as each forty miles of said railroad and telegraph line are completed, upon certificate of said commissioners. Any vacancies occurring in said board of commissioners by death, resignation, or otherwise, shall be filled by the President of the United States: Provided, however, That such commissioners shall be appointed by the President of the United States unless there shall be presented to him a statement, verified on oath by the president of said company, that such forty miles have been completed, in the manner required by this act, and setting forth with certainty the points where such forty miles begin and where the same end; which oath shall be taken before a judge of a court of record.

Ratchet Wrench

The most common type of socket wrench is the ratchet socket wrench, also known as a ratchet. A ratchet is a handheld metal tool that uses a ratcheting mechanism to tighten or loosen bolts and nuts, known generally as fasteners. The ratcheting mechanism allows for quick adjustment of these fasteners because the ratchet stays connected during adjustment. This speed is attributed to a lever that allows the user to switch between

loosening and tightening modes quickly and with ease. The ratchet has interchangeable sockets, which are usually hexagonal, to correctly fit the size of the fastener. The sockets are connected to the handle of the ratchet via a driver, which can come in various sizes. In general, the size of the driver and the amount of torque are directly proportional.

In the mid-1800s, *Scientific American* magazine opened a patent agency to encourage the development of new technology and ideas in the United States.

The best ideas that it received were then featured in the magazine as a reward. J. J. Richardson of Woodstock, Vermont, created the ratchet as part of this campaign. The idea was inspired by the old socket wrenches of the Middle Ages—those that were used as keys to wind up clocks. During that time, many of the sockets were square because of manufacturing limitations. As technology improved, however, hexagonal sockets became more popular. Although the socket wrench has been around for several centuries, the ratcheting socket wrench—combining the ratcheting mechanism with interchangeable sockets—was a novel idea. Richardson patented his new invention through the Scientific American Patent Agency in 1863, and an illustration of his ratchet was featured in *Scientific American* in 1864.

Richardson's invention became a necessity in every mechanic's toolbox. As a result, hexagonal heads and sockets have also gained popularity. With modern technology, it has become increasingly easier to mill, broach, and shape hexagonal pieces to replace the outdated square components of the earlier centuries. Drive fittings now come in four standard sizes: one-quarter inch, three-eighths inch, half inch, and three-quarters inch. These sizes are trade names; they are actually constructed using these rounded metric equivalents: 6.3 mm, 9.5 mm, 12.5 mm, and 19 mm. After Richardson constructed the original ratchet, many other similar tools have been invented.

The click-style torque wrench and flex-head ratchet are the most commonly used offspring of Richardson's ratchet. The click-style torque wrench clicks when a preset torque is achieved. This torque value is displayed digitally on the tool itself, or the tool slips off the fastener when the required torque value is reached. The flex-head ratchet has a swiveling head. The drive head rotates in opposite directions on a pivot near the back. There are many other types of ratchet wrenches, all inspired by the original. These ratchets vary by size, manufacturer, and other features.

Relay

The electromechanical relay was invented in 1835 by scientist Joseph Henry (1797–1878), a pioneer in electricity and magnetism. His relay was an electrical switch that used an electromagnet to open and close contacts in a circuit.

Relays consist of an iron bar tightly wrapped with a coil of wire (an electromagnet), a movable armature, and a set of electrical contacts. When electricity is applied to the wire, it creates a temporary magnetic field. Reversing the electric current changes the polarity of the magnetic field, and turning off the current collapses the magnetic field. The relay thus operates as an on-off switch.

It was not until the 1860s that Henry's invention became widespread—when it was incorporated into the telegraph and, later, the telephone. Relays were also used to construct Boolean logic circuits that could perform basic binary arithmetical operations. These circuits later formed the backbone of the first mechanical computers.

Repeating Rifle

Long-barrel guns have been used by hunters and soldiers for centuries. A gun with a long barrel that is pressed against the shooter's shoulder to fire is a rifle. Early rifles fired one shot at a time. It took decades of experimentation and hard work to design and manufacture a multiple-shot, or repeating, rifle.

Early muzzle-loaded gun barrels were smooth on the outside and inside. Gunpowder was necessary for ignition when firing a gun, and unburned powder

residue accumulated inside the barrel. A straight-groove rifle or cut inside the barrel decreased this residue buildup. Cutting a curved or spiral groove worked even better and had the added positive effects of increasing the shot's range and improving its balance and stability. Rifles were known for their accuracy.

Loading a gun was a multistep process. Gunpowder was poured down the barrel's muzzle, followed by a lead ball. A small amount of gunpowder was put in the flash pan. The gun's cock held a piece of sharp flint (this is a hard mineral) that sparked when hit. When the trigger was pulled, the flint sparked, igniting the gunpowder, and the lead ball was pushed down the gun's barrel by the force of the explosion. Then the next lead ball was loaded.

John Hancock Hall (1781–1841) invented a breechloading, single-shot rifle and patented it in 1811. Hall worked at the rifle works at the U.S. Armory at Harpers Ferry, Virginia (now West Virginia), where he improved the rifle's performance. Hall later patented a breechloading, single-shot rifle that used percussion-cap ammunition.

Percussion caps were an improvement. The cap was placed over a small raised area at the rear of the gun barrel. Pulling the gun's trigger released the hammer, which struck the cap and ignited the explosive material (held in a metal container that was closed at one end). This then ignited the gunpowder and pushed the bullet down the barrel.

The next step in rifle development would be from single shot to multiple shot, but progressing from one to the other required more than redesigning the gun. Ammunition needed to be more uniform and easier to load.

Walter Hunt patented his Rocket Ball ammunition in 1848. The Rocket Ball consisted of a hollow cartridge filled with gunpowder. The back or rear part of the cartridge was sealed with a cap that had a small open hole. Hunt designed a gun (called the Volitional Repeater—later, the Volcanic) that fired this ammunition. The gun's tube-shaped magazine was under the barrel. The shooter's finger pressed a spring-loaded lever to feed ammunition into the breech.

The following year, Lewis Jennings patented improvements to Hunt's rifle. This gun was manufactured at Robbins & Lawrence Company in Vermont. Horace Smith and D. B. Wesson bought Jennings's

patent in 1854 and improved the lever-action gun. They improved the ammunition by adding a fulminate-backed metal disk to the rear of the Rocket Ball cartridge. Since primer surrounded the rim of this cartridge, no percussion cap was needed. It ignited when struck anywhere along the rim. Smith and Wesson formed the Smith & Wesson Company in Connecticut, but they changed its name to Volcanic Repeating Arms Company in 1855.

An investor in Volcanic Repeating Arms was Oliver Winchester (1810–1881), a New York City businessman. Though Smith and Wesson left the company in 1857, it kept the rights to the gun and ammunition. Winchester, as majority stockholder and a vice president in the company, became president. Volcanic Repeating Arms was renamed the New Haven Arms Company. Former Robbins & Lawrence shop foreman Benjamin Tyler Henry (1821–1898) was hired as plant superintendent.

Henry was an experienced gunsmith. Henry developed a brass cartridge in 1859 that was longer than currently used lead cartridges, so it held more powder. The brass cartridge expanded upon firing and created a better seal between casing and breech. Henry developed a rifle to fire this ammunition and patented it in 1860.

The Henry rifle's magazine tube held 15 cartridges. To fire the rifle, the trigger guard lever was pushed down and forward to eject the spent or used casing out the top of the gun's breech, forcing a fresh cartridge into a lift mechanism and cocking the gun's hammer. The rifle was then ready to fire.

One disadvantage of the Henry rifle was that the end of the gun's magazine tube had to be unfastened to reload cartridges. A competing rifle, the Spencer, had a latch on the end of its rifle buttstock that was hinged so that the empty magazine tube could be removed and an already-loaded magazine put in place. Shooters carried a pouch with preloaded magazine tubes.

New Haven Arms Company's name was changed to Henry Repeating Rifle Company in 1865. Winchester remained president, and the following year, the company was renamed Winchester Repeating Arms Company.

The 1866 Model Winchester corrected some issues with the previous model. Since repeated firing caused the rifle barrel to heat up, a wooden piece was placed over the barrel so a shooter's hand would not be

burned when touching it. To make reloading easier, a rear spring-loaded mechanism was added. This model was manufactured for 32 years.

The Winchester Company produced many variations of guns. The Winchester Model 1873 rifle had an iron frame and the 1884 model a steel frame. The Model 1894 was the first sport rifle to exceed 1 million in sales. President Calvin Coolidge was given the millionth rifle produced in 1927, and President Dwight Eisenhower the 2-millionth rifle in 1953. Over 7 million have been manufactured.

Rifles and repeating rifles remain popular today, and Winchester Repeating Arms is still in operation.

Roller Skates

John Joseph Merlin is given credit for inventing the first roller skates in 1760. They were inline skates, not quad skates. Quad skates were invented in 1863 by James Leonard Plimpton. They have four wheels each in two side-by-side pairs, front and rear. The skates allowed the skater to turn or pivot by leaning to one side or the other. Soon, roller rinks were opened. The first roller rink opened in New York City in Plimpton's own furniture store. Another soon followed in Newport, Rhode Island, also involving Plimpton's support. The quad skate became the most popular style of skating for more than a century.

People continued working on improving the roller skate. In 1876 an Englishman, William Brown, patented a new design for the wheels of roller skates. Brown worked with Joseph Henry Hughes, the patent holder for a roller bearing for carriage wheels and

The roller-skating craze reached its peak in the 1920s with skating marathons or derbies. While young people loved roller skating, social conservatives disapproved. Some cities banned the sport from streets and sidewalks. (Library of Congress)

bicycles that included an adjustable system for the wheels. This allowed for both a fixed and a moving axle in the skates. This might have been the most important advance in roller skates and is the basis for the modern skateboard as well as modern skates. In 1876, the toe stop made its appearance. It allows the skater to stop by raising the back of the skate and resting the toe stop on the ice. By the 1880s, thousands of skates per week were being mass-produced. The adjustable skate screw was invented to adjust the skate over a shoe more easily.

In 1902, the modern inline skate appeared. Inline skates have anywhere from two to five wheels in a single line. Generally, recreational inline skates have a toe stop on the frame's rear. Inline skates resemble ice skates because they were developed to be a substitute for them. The original American patent for inline skates was issued in 1953 to Ernest Kahlert. These

skates were not commercially available until 1987 and were made by Rollerblade.

Roller skates appear to go through periodic booms. One such boom came with the birth of disco, with the marriage of disco and roller-skating. At its height in the late 1970s, over 4,000 disco roller-skating rinks were open, and roller disco movies were in fashion. Meanwhile, design and safety has continued to improve. In 1993, Rollerblade Inc. developed a safer and better way to brake Active Brake Technology (ABT). In this system, a fiberglass post was attached at one end to the top of the boot and at the other end to a rubber brake, which is hinged on the chassis at the back wheel. The skater must straighten one leg to stop, pushing the post into the brake so that it hits the ground. This is an improvement on the traditional technique of toe braking or even heel braking.

Given the number of contact sports that have come out of roller skating, increased safety is important. There is hockey played with roller skates instead of ice skates, racing, and—one of the more popular sports—roller derby. Roller derby grew out of the marathon racing of the 1930s, which was done around banked, indoor tracks. It is a contact sport played by two teams of five members and is dominated by women. Modern roller derby as we have come to know it is credited to Leo Seltzer and Damon Runyon. In the late 20th century, roller derby began to resemble professional wrestling, with show-business touches and scripted winners. In the 21st century, these touches were given up, and it returned to its grass roots.

Roller skates have come to be an important part of American recreation and sports. They continue to undergo improvements and to be popular as a form of entertainment and exercise.

Rotary Hook (for Sewing Machines)

Allen Benjamin Wilson patented the rotary hook and bobbin for sewing machines, which eventually replaced a shuttle mechanism, in 1851. The purpose of a rotary hook is to open the needle's thread loop. In turn, the lockstitch was completed by a reciprocating bobbin that carried a second thread through the loop that the rotary hook had opened. A year later, Wilson replaced the reciprocating bobbin with a stationary one. These improvements led to a revolutionary change in sewing.

Allen Benjamin Wilson (1824–1888) was born in Willett, New York. He became a cabinetmaker, apprenticing at the age of 16. In 1847, he left New York State for Adrian, Michigan, to pursue that profession. After patenting sewing machine ideas, he joined forces with Nathaniel Wheeler, who was a partner in Warren and Woodruff in Watertown, Connecticut. Wilson moved there and continued to perfect his sewing machine.

Wilson used a commercial Wheeler and Wilson machine for obtaining his rotary hook patent. Wheeler and Wilson founded a new company to manufacture his revolutionary machine, and in 1856, the company moved to Bridgeport, Connecticut, where it became the most prominent and successful producer of sewing machines in the period.

Rucker Ambulance

The Rucker ambulance was designed by D. H. Rucker for use during the American Civil War. It was one of the most useful ambulances then because it could transport four patients at once. Rucker's ambulance saw heavy battlefield use, and it was also used after the war. Although different ambulance designs were

drawn up afterward, none could dethrone the Rucker as the most useful of the mid-19th century.

Before the Civil War, the U.S. military had no feasible means to transport the injured either during war-time or peace. The first ambulances were two-wheeled, horse-drawn wagons that could transport two to three people at a time. Prior to the Rucker ambulance were the Finley and the Coolidge, but they were not seen as field ready or suitable to transport wounded and injured. As the use of ambulances rose during war-time, more and more were designed.

The Rucker, like the other ambulances, was a four-wheeled, horse-drawn version most commonly used on battlefields. It could carry up to four patients. The rear had two seats with compartments that could be lowered to make additional space for stretchers to accommodate injured soldiers. The compartments were also ventilated when all the sides of the wagon were opened.

After the Civil War, the Rucker ambulance made its way into regular civilian life and was used until the introduction of the Terre Haute ambulance.

Safety Pin

A safety pin is an object used in place of buttons, hooks, or zippers to fasten clothing. Inventor Walter Hunt, also responsible for building America's first sewing machine, twisted wire into the pin's

rudimentary shape and saw the possibilities. He coiled the wire into a spring at one end and a separate clasp and point at the other, which allowed the point of the wire to be forced by the spring into the clasp. He claimed that the clasp would keep fingers safe. For his work on the safety pin, Hunt was granted U.S. Patent 6,281 on April 10, 1849. Sadly, Hunt sold his patent for \$400 to pay off a debt.

Hunt's later inventions include a forerunner of the Winchester repeating rifle, a successful flax spinner, a knife sharpener, a streetcar bell, a stove that burned hard coal, artificial stone, road-sweeping machinery, velocipedes, ice ploughs, and mail sorting machinery.

Sewing Machine, Automated

Like most significant events in business, an invention, or series of inventions, acts only as the seed for full commercialization. The market decides the usefulness of an invention, and the workplace determines the speed of implementation. The advent of the automated sewing machine is the perfect example of the process of commercialization of an invention and the evolution of a manufacturing process. The more classless society of America in the 19th century brought on a curious distinction from that of Europe. The lower- and middle-income groups had a propensity to dress well, approaching the dress of the wealthy. Tailors and seamstresses came together to "manufacture" clothing in factories such as the Quincy Hall Clothing Manufactory in Boston and Opdyke Manufacturing in New Orleans. Still, prior to 1850, just as Alexander Hamilton had reported in his 1794 *Report on Manufacturing*, about 70 to 80 percent of American clothing was handmade. There was, however, a huge potential market if prices could come down. The automated sewing

machine would lead to a revolution in ready-made clothing.

Tailors were considered skilled craftsmen and formed guilds and unions. They were generally immigrants and were very sensitive to the automation of their crafts; the power loom had created major unemployment in the crafts in the early 1800s in Europe. In England, a group known as the Luddites had burned and destroyed power looms from 1811 to 1813. Similarly, in 1841, French tailors had destroyed a factory of 80 semiautomated sewing machines, fearing job loss. In America, there was less pressure, but tailors still resisted automation. The market potential, however, could not hold back creativity in the United States. The French sewing machine and early American machines of the 1830s showed little promise, but creativity continued, driven by the market. One of the first machines was that of Walter Hunt, but he discontinued its development, fearing that low-wage seamstresses would lose their jobs. Not surprisingly, several other inventors appeared on the scene simultaneously in the 1840s.

One of the first successful patents for automated sewing machines was that of Elias Howe in 1846. The Howe machine had many limitations, such as being hand cranked, had a limited seam length, and had to be readjusted often, but it did serve as inspiration for further development by others, including Isaac Singer. He improved on the Howe machine; for one thing, it was driven by a foot pedal. He faced an army of lawyers defending the Howe patent, but Singer proved the better salesman, successfully selling his \$2,000 machine to factories. Ultimately, Singer lost a patent infringement case to Howe; Singer had impacted the market and chose to pay royalties to Howe. A number of inventors entered the battle, which became known as the “Sewing Machine War” and would augur future legal battles over inventions in America. At least 10 inventors had received patents on machine improvements, particularly regarding thread-feeding systems and types of stitch.

While the sewing machine did reduce clothing costs and allowed for more customization, manufacturing companies became bogged down with patent infringement cases. Various inventors had keys to full automation; for example, Benjamin Wilson’s 1849 patent for automated thread feeding was as critical as

Howe’s and Singer’s features. The manufacturers brokered an 1856 deal between the inventors, which was known as the “Sewing Machine Combination.” The various patent owners pooled all their features for the sewing machine into a single fee, and they also had the franchising rights for manufacturers. Howe, whose machine had never been a commercial success, became the highest paid of the inventors, receiving \$5 per machine sold. The others shared a royalty of another \$10 per machine. The combination agreement remained in effect until 1877. Years later, General Electric and Westinghouse Electric would use this patent-pooling business model to end the “war of the currents.” Today, such arrangements would not meet the test of our antitrust laws.

The Singer sewing machine not only revolutionized the clothing industry but also automated the shoe industry by 1860. The Civil War and President Abraham Lincoln’s domestic manufacturing and tariff policies created the ready-made clothing market. The government submitted a type of standard sizing for military uniform manufacturers, who used this statistical normal distribution of human sizes to develop the science of sizing—that is, that certain measurements occurred with predictable repeatability. The combination of automation and market made clothing America’s major business in 1870. The clothing market doubled from 1860 to 1870 and reached a billion dollars by 1890. Similarly, the shoe market grew. The sole- sewing machine in 1858 revolutionized shoe manufacture. Ready-made, standardized shoes took over the market by 1890. Now, a customer knowing his or her size could shop at the newly emerging department stores of the 1890s. Sewing machine sales from 1860 became an international market, which the United States dominated.

Singer proved the best marketer, and by 1865, he controlled 70 percent of the market. In 1877, Singer went on to add the continuous-stitch feature and formed the Singer Sewing Machine Company. Singer electrified his machine first in 1889 to further increase productivity. The time to make a simple dress dropped from 10 hours for handmade to under 1 hour with machines in 1890. The skill level dropped from that of a craftsman tailor to that of a simple laborer. Automated sewing led to labor specialization and subassembly operations. The automation further led to the

“sweating” system (task system) in which subcontractors opened small shops in the poor districts of New York and Chicago. These shops used cheap immigrant women workers. The manufacturers cut the cloth, marked the parts, and enclosed instructions for the subcontractors, allowing for a form of standardized mass production. Individual families even got into the bidding process, working out of their homes. The bidding among subcontractors drove costs and prices down. The system of subassembly and bidding is an early example of supply chain management. Abuses would lead to a general strike in 1910 of 40,000-plus immigrant garment workers. The strike led to the formation of the United Garment Workers and the Amalgamated Clothing Workers of America.

Sewing Pattern

The tissue sewing pattern was developed by Ellen Curtis Demorest in the 1850s. Her inspiration came one day as she watched someone cut out a pattern on rough wrapping paper. She reasoned that producing a pattern on thinner paper could be easily done and the resulting patterns distributed at low cost. She and her sister, Kate, had been working on numerous ways to accurately cut out dress patterns. After working on various charts for seven years, they felt that they had accomplished this task.

Ellen Demorest was born in 1825. Raised in Ballston Spa, near Saratoga, New York, she had a simple but comfortable upbringing. Her father owned a hat factory where the bestselling hats cost \$20 and up. With the opening of the Erie Canal and the railroad extension into Saratoga, the area became prosperous

as new kinds of businesses appeared. During the 1840s, as the town became a popular resort area that the wealthy visited during the summer. From watching the wives and daughters of rich men, she developed a keen interest in ladies' fashion.

After graduating from Schuylerville Academy, Demorest decided to become a milliner. Millinery—designing, producing, and selling ladies hats—was considered an acceptable vocation for respectable women. Her father helped his daughter by giving her money to start a small business. By the end of the first year, Demorest relocated to Troy, New York, known as the center for millinery, where she soon became a superintendent of an established business. She met her husband, William Jennings Demorest, in Troy.

Together they worked on improving on the logistics of tissue patterns to make them more accessible to the population. The main goal was to ensure that dress patterns reflected ladies various shapes and sizes. The Demorests began by displaying a small collection of these tissue paper patterns to local women. Mr. Demorest sought to market the patterns broadly and quickly. In 1860, he published the first issue of *Mme. Demorest's Mirror of Fashions*, a 10-cent quarterly publication designed in blue with gold decorations on the cover. The paper patterns were also heavily advertised with a sample and became so popular that the Mme. Demorest's name became linked with her invention.

The Demorests' pattern business grew rapidly. All over the United States, women clamored for the dress patterns. By using the samples in the magazine, they could learn how to cut and sew the dresses. Pattern prices varied according to the article of clothing. Patterns for mantillas, basques, and bodices were less expensive than patterns for high-fashion dresses. The patterns were printed on tinted paper and were sold at retail stores, by mail order and at dressmakers' shops.

The Demorests' business continued to thrive for another two decades until the 1880s. For some unknown reason, they never patented the tissue paper pattern. Ebenezer Butterick saw this as an opportunity. Butterick created paper sewing patterns for children between the ages of three to five and patented them. The customized patterns for children proved to be a success. Butterick expanded his business in 1863 by selling men's and boys' patterns according to size.

Three years later, he added patterns for women's clothing—these were sized using a system based on bust measurement. As his business expanded and thrived, he ventured into magazines and founded the *Semi-Annual Report of Gent's Fashions* in 1865. By the 1870s, he was also publishing the *Ladies' Report of New York Fashions* and *The Metropolitan*, a monthly offering that covered literature and fashion, including Butterick's sewing patterns. *The Metropolitan* would change its name to *The Delineator* in 1875 and continue publication until 1936.

Sewing patterns continue to sell well in the United States. Simplicity, McCall's, Vogue, and Butterick all have a considerable presence in most fabric stores.

Solar Compass

The solar compass is a device used by surveyors to determine the four cardinal directions (north, south, east, and west) using the position of the sun. It provides accurate survey results in areas where magnetic compasses malfunction.

There have been many variations of magnetic compasses since the Chinese used a lodestone (magnetite) in the first century. Compasses used in 19th-century America consisted of a magnetized needle on a pivot in a case. The needle rotated on the pivot, orienting with the earth's magnetic field to point north.

Magnetic compasses are very reliable close to the equator, but their accuracy decreases as latitude increases. Moving away from the equator and the accompanying fluctuations in the earth's magnetic field affect their ability to determine magnetic north. Large ore deposits also interfere with their accuracy.

U.S. Deputy Surveyor William Austin Burt (1792–1858) worked in the Midwest (Michigan, Wisconsin, and parts of Iowa) and found results in certain areas of these states were erratic so not always verifiable. These problem areas contained large mineral deposits such as iron ore that caused magnetic compass needles to spin nonstop. If a needle did stop, it gave incorrect results. Burt thought the iron deposits in these areas were large enough to interfere with the accuracy of compasses, so he invented a solar compass.

Made of brass, the solar compass is a combination of zinc and copper and therefore not magnetic. It consists of an upper and lower plate. The upper plate displays a needle box and three arcs. One arc is set to the latitude of the survey area, the second arc is set to the sun's declination (the sun's degree of angle in the sky based on time of the year), and the third arc is set to the hour of the day. The compass sights are on the lower plate, and it has a set of convex lenses. The apparatus is attached to a tripod for stability. Its results are accurate in areas with or without mineral deposits and at any latitude.

Burt patented the solar compass on February 25, 1836 (patent number 9428). Improvements were made over several years, and Burt received two additional patents—one in 1840 and another in 1851. Since Burt's solar compass was not affected by latitude, mineral deposits, or fluctuations of the earth's magnetic field, it was used for almost 150 years. The solar compass remained a valuable resource until the late 20th century, when global positioning system (GPS) technology was introduced.

Spar Torpedo

The spar torpedo was first devised in 1810 by the inventor Robert Fulton, who designed, but never built, torpedo boats that would fire harpoons into enemy ships; the harpoons would then reel explosives in and a second rope would be pulled to start the clockwork detonator.

When the spar torpedo was resurrected during the Civil War, Fulton's elaborate mechanism was abandoned in favor of a simpler mechanism. The navy of the Confederate States of America was sorely outclassed by the U.S. Navy; to break the blockade of Southern ports, the Confederacy turned to a number of experimental weapons, including ironclads, submarines, and spar torpedoes.

The version used by the Confederacy was invented by E. C. Singer, who made his name by manufacturing naval mines. Singer was hired by the Confederate Engineering Department, along with his crew, to conduct spar torpedo attacks using the *H. L. Hunley*, a primitive submersible that Singer had also helped to develop. Singer's torpedo was carried on the end of a long boom in front of the *Hunley* and was detonated using a spring mechanism.

While the *Hunley* was still being constructed, another Confederate group used a spar torpedo on a small boat to badly damage the USS *New Ironsides* on October 5, 1863. The *Hunley* was the first submarine to sink a ship when it attacked the USS *Housatonic* on February 17, 1864. It had been long assumed that the spar torpedo was a suicide weapon and that the blast must have knocked some of her crew unconscious, but the *Hunley* was observed firing a flare to indicate a successful mission, and its wreck was discovered in 2000 not far from Charleston's harbor.

The U.S. Navy adopted the spar torpedo and used it to sink a Confederate ironclad in October 1864. Before long, slightly longer and safer spar torpedoes were in service with many navies. The Russian Navy used them extensively in wars against the Ottoman Empire, and a French punitive expedition in China used them to sink several gunboats in a single battle.

While spar torpedoes were not phased out until around 1900, they were used rarely; naval combat took place at increasing distances as gunnery improved.

Most of these torpedoes were mounted on small, fast boats in hopes of getting close and evading an enemy ship's heavy guns before attacking. The spar torpedo was nearly revived in 1945, when a desperate Japan trained a small unit of kamikaze divers to thrust explosive spears against ships at arm's length. Most of that unit died in training, and it was disbanded at the war's end without seeing action.

Steam Locomotive

A steam locomotive used the power of steam to move pistons mechanically connected to the main wheels of the vehicle rather than gas or solar energy and was prevalent in the United States in the 1800s. The steam was created on board by burning various combustible materials, which most frequently included coal and wood, in a boiler.

U.S. President Abraham Lincoln (1809–1865) understood both the challenges and vital importance of transportation in America. With such a huge landscape to cover from the Atlantic to the Pacific, Lincoln grasped the fact that canals and rivers simply could not be expected to keep pace with the country's growth, even with the powerful steamboats that plied the waterways. Nor could they provide the means for continued growth—there was just too much space to cover in the vast new country. As a former riverboat pilot, he knew that a more robust means of transporting goods and people would be crucial. He did not live to see the completion of the Transcontinental Railroad on May 10, 1869, but his vision for the United States—replacing regional loyalties with a sense of national destiny—came true.

The Transcontinental Railroad would not have come to fruition without the technological innovation of the steam locomotive—the “Iron Horse”—that powered it. The invention of the steam engine drove the Industrial Revolution in America, changing the way things were made and delivered to people all over the world. It changed the destiny of entire towns as well as the way of life for most people as the American economy diversified from being centered on agriculture to an industrial powerhouse. It brought people from around the globe to their new homes on the vast American continent. It created the American dynamo. Such was the power of the steam-driven Iron Horse.

The development of the steam locomotive dates back to 1763 with Scottish inventor James Watt’s improvements to the steam engine. The first full-scale steam locomotive was built in Britain by Richard Trevithick in 1804, though at the time, his steam locomotive was not well received.

Still, visionaries in the United States could see the potential. The Baltimore and Ohio was incorporated in 1827, with other rail companies soon to follow. In 1829, the Stourbridge Lion, brought from England, was the first steam locomotive in the United States and was tested along tracks built by the Delaware and Hudson Canal Company, which was diversifying for the future. The first steam locomotive to be built in America, Peter Cooper’s *Tom Thumb*, had its first run in 1830. It cruised at 18 miles per hour and carried 36 passengers. That same year, a steam locomotive known as *The Best Friend of Charleston* began regularly carrying passengers.

Along with hauling people, the steam locomotive transported goods at a much more rapid rate than was possible by horses or waterways. The railroad enabled people to know exactly when and where their goods would arrive. Despite what Hollywood westerns depict, trains also gave people and cargo a safer ride, as it was much more difficult to rob a train than a canal boat or horse-drawn transport. As more railroads were built, people and products could travel farther and faster than ever before.

Technological innovation kept advancing the steam locomotive, though it had begun as a relatively simple concept. The heart of the steam locomotive is a steam-powered engine. Fire is used to create heat, which boils water. This produces steam, which is

released into pipes. Pistons are connected to the locomotive’s wheels. As valves release the steam into chambers, which moves the pistons, the wheels move. By adding as many freight or passenger cars as the locomotive could pull, a remarkable new age was born.

Rail travel via steam locomotives caught on—well, like a runaway train. In 1830, the year the *Tom Thumb* had its first run, there were less than 25 miles of railroad tracks in the United States. Within 20 years, there were more than 9,000. There was a good reason for this: the federal government passed its first Land Grant Act in 1850, opening about 180 million acres for railroad construction. The idea was to encourage railroad growth and help offset the financial burden of building and developing rail lines.

The Land Grant Act was also designed to attract settlers to the vast, undeveloped parts of the country in the West. The Act granted 10 square miles of federal land for every mile of rail built. During the legislative life of the Act, which ran until 1871, once-unwanted land became valuable. Native Americans were squeezed out. Much of California and Texas was closed to homesteading as so much prime land had been granted to railroad companies. Yet, once the government perfected the technique of granting land to the railroads, Congress enabled a similar piece of legislation: the Morrill Land Grant Act in 1862. That Act deeded almost 20 million acres of land to the individual states; they could sell the land and use the proceeds to endow at least one college. This was the genesis of more than 70 “land-grant colleges,” especially in the West, which helped build the nation along with the steam locomotive as the catalyst.

By the beginning of the Civil War in 1861, there were 30,000 miles of track. Over 21,000 of them were in the North. Throughout the war, railroads allowed the quick transport of large numbers of soldiers and heavy artillery over long distances. After the Battle of Chickamauga in 1863, Abraham Lincoln was able to send 20,000 badly needed replacement Union troops over a thousand miles from Washington, D.C., to Georgia. It was called the longest and fastest troop movement of the 19th century. The steam locomotive was a powerful factor in the North’s ultimate victory.

Even in wartime, a steam-powered transcontinental rail line was an important goal of Lincoln’s.

Through the land grants and low-interest government loans, entrepreneurs were encouraged to take on the challenge of laying rail from coast to coast. In 1862, these included California's "Big Four": Charles Crocker, Collis Huntington, Mark Hopkins, and Leland Stanford. However, the backbreaking work of doing so was done by immigrant men and women, mostly Chinese and Irish.

Ironically, Lincoln continued fostering steam-powered rail travel even after his death. Chicago's George Pullman had the idea of a comfortable railroad "sleeping car" after a particularly uncomfortable train ride he had taken in upstate New York. By 1863, he had produced his first two models, but they were too expensive for rail companies. After Lincoln's assassination in 1865, Pullman offered one of his railcars as part of the funeral cortege that traveled through several states, bringing Lincoln's body home to Illinois. Those people who did not line the tracks to see the steam-powered train could at least read about Pullman's railcar on the front pages. Publicity poured in about Pullman loaning one of his sleeper cars to the grief-stricken Mary Lincoln. The connection continued with Pullman's death in 1897 when Robert Todd Lincoln, the slain president's eldest son, became head of the Pullman Company.

Powered by the steam locomotive, the number of miles of railroad track climbed steadily until hitting its peak in 1916, when there were more than 250,000 miles of track—enough to reach from Earth to the moon. The impact of the technological innovation of the steam locomotive cannot be overstated. It enabled all forms of long-distance travel, from settling the West to carrying raw materials and finished goods to waging war. It united the far-flung parts of the country, boosted economic development, and was the catalyst for America's rise to the pinnacle of a world power.

Technology and innovation do not exist in a vacuum. Their value is often determined in unexpected ways, often transforming society. This was especially true of the steam locomotive. In the 19th century, railroads determined the fate of American towns both large and small. Those on the rail line flourished; others often withered. Especially in the vast expanses of the American West, towns on the steam-driven rail lines were connected to the rest of the world.

New terminology was coined during the heyday of the steam locomotive, including such literal terms as

"cowcatcher" and "bells and whistles." Since steam-driven locomotives needed water to create the steam, they had to stop frequently for replenishment. Some communities were too small to have refilling facilities, so rail crews had to stop next to streams and use buckets to fill the tender with water. Since they had the annoying task of "jerking" the water, communities too small even to have a water tank were derisively called "jerkwater" towns.

The steam-powered locomotive created American jobs. In the first place, tracks had to be built on which trains could travel. As time passed, greater demand for expanded rail service created the need for more track in more areas. Both locomotives and railcars had to be made and supplied all over the country. Then, as more people had access to goods, increased sales and greater demand drove factories around the nation to hire more people.

The steam locomotive even stimulated growth in one specific professional field: architecture. Rail depots had to be designed and built, with many having their genesis as "union stations," where tracks and facilities were shared by several rail companies, allowing passengers to connect conveniently between them. A few included Union Station in Columbus, Ohio, which first opened in 1850. The Indianapolis Union Station opened in 1853. Chicago and Denver each had union stations dating to 1881. Many were designed to have long-term architectural value instead of being simply boxes with tracks running through them.

Steam locomotives also had an impact in less obvious though far-reaching ways. For the first time, isolated communities were not subject to the threat of famine if there was a drought or disease that killed their crops, because more food could be brought in by rail. People were also safer, only having to travel to the nearest train depot to pick up goods and supplies rather than make long treks across hostile country to more urbanized areas to stock up. A whole new world was opened up for women who, prior to the advent of the steam locomotive, rarely traveled without escorts and had to slowly cross long distances by horse and wagon—easy targets for marauders.

By the 1920s, however, diesel and electric trains began to take the place of steam locomotives. Automobiles, trucks, airplanes, and the Great Depression of the 1930s all contributed to a general decline in

railroad ridership. By the 1950s, most passenger rail travel had dropped significantly. But in its heyday from the 1800s to the mid-20th century, the steam locomotive played a vital role in the survival, growth, and ultimate economic dominance of America.

Steam Shovel

A steam shovel digs up and transports rocks and soil. Patented in 1839 by William Otis, who was only 22 years old at the time, the Otis steam shovel is considered the earliest excavator. The steam shovel played a major role in the construction of railways as well as the Panama Canal during the 1800s and early 1900s.

The drawing of the steam shovel from Otis's 1839 patent is officially "missing," but a drawing has been found depicting a crane connected to a railroad car; the general consensus is that this was actually Otis's sketch. Otis started inventing his machine in 1835, when he was only 18 years old. Working with Carmichael and Fairbanks, he used a railroad segment between Norwich and Worcester, Massachusetts. After this initial machine was tested, Otis moved to Philadelphia to work alongside the operator of Garrett and Eastwick: the reputable Joseph Harrison. Together, they created a model for the steam shovel and even received a patent in 1836. However, their designs were soon destroyed in an unfortunate fire. Over the next three years, Otis worked to recreate and later improve what had been lost. In 1839, he received a patent for

what he called a "Crane-Excavator for Excavating and Removing Earth," soon to be known as the "steam shovel." Less than a year after his patent was issued, William Otis passed away at the early age of 26.

The steam shovel had three main components—the bucket, the "dipper," and the "boom." The bucket was connected to the boom via the dipper and was used to dig and move earth. Coal was used to boil water and create steam, which powered the shovel. The shovel itself could rotate as well as move the boom and the dipper to perform the required operations. The dipper stick was repeatedly moved to fill the bucket with dirt and rocks. Once the bucket was full, the shovel could be rotated to fill up a nearby railroad car or other receptacle to remove earth from the area.

Steam shovel crews typically consisted of three people: an engineer, a fireman, and a ground man. Each person was completely necessary because there was a lot of hard work to be done not only to move earth but also simply to move the shovel into the right location and position. Earlier models used their own booms to maneuver themselves; they were not propelled by any other means.

The steam shovel's popularity grew as a result of the railroad industry. Railroad construction required large amounts of material to be moved for miles and miles. Steam shovels were put to work all over the country to help with the cause. Some of the fastest-growing cities even used the steam shovel to dig skyscraper foundations. The shovels were especially useful in digging mines—Minnesota iron mines and the Klondike mines, among many others—but the open-pit mines in Bingham Canyon, Utah, were some of the most memorable. Steam shovels literally removed hills over a period of time. These mines would serve as examples to other countries, including Australia and China. It was not long before the steam shovel was in use all over the world. The most notable example of the great technological prowess of the steam shovel was the decade-long construction of the Panama Canal, built by the United States from 1904 to 1914. Over 100 steam shovels were used on the project, most of them manufactured by Bucyrus or Marion Steam Shovel Company.

Although William Otis's steam shovel served a great purpose in American history, it is no longer used as a

President Theodore “Teddy” Roosevelt near the controls of a steam shovel at the construction site of the Panama Canal in 1908. Steam-powered machinery like this shovel allowed for larger, more complicated building projects. (Library of Congress)

method of excavation. During the 1930s, diesel-powered shovels took over the industry due to their simple design and inexpensive price. Other multiton shovels have been manufactured for specific projects after the fall of the steam shovel era; they are known as power shovels because they use electricity instead of steam. Most steam shovels have been dismantled, but a few remain in museums or private collections in remembrance of such a monumental technological advancement.

Stevens, Robert Livingston (1787–1856)

Robert Livingston Stevens was a member of a family of engineers whose inventions improved transportation on land and water. Stevens, born on October 18, 1787, in Hoboken, New Jersey, was one of the 11 children of John Stevens (1749–1838) and Rachel Cox Stevens. John, known as “Colonel” from his service as treasurer of New Jersey during the Revolutionary War, had come from a wealthy family, and after graduating from King’s College (now Columbia University) and then studying law, had become interested in mechanical engineering. Having to commute slowly by boat

between houses in lower Manhattan and Hoboken, John was intrigued by the earlier experiments of John Fitch and James Rumsey with steamboats. John persuaded Congress to pass the first patent law in 1790, and a year later, he took out three patents related to steamboats and a multitubular steam boiler. Working with both his brother-in-law Robert Livingston (who was chancellor of New York and had obtained Fitch's monopoly of the right to navigate steamboats in that state) and Nicholas Roosevelt, John launched his first steamboat, the *Polacca*, in 1798, but it was not a successful design. The three men, however, agreed to be partners in steamboats for 20 years.

Robert worked closely with his father, including the design and construction of the *Little Juliana*, the first twin-screw-propelled steamboat, which Robert and his older brother John Cox Stevens successfully operated across the Hudson River in 1804. The boilers and engines of that era, however, could not produce the high pressure needed for screw propulsion, so Robert and his father reverted to the paddle wheel on the *Phoenix* (1808), which Robert designed with concave waterlines. The adoption of the propeller for steam navigation would begin after both Francis Pettit Smith (1808–1874) and John Ericsson (1803–1889) received patents for screw propellers in 1836.

The *Phoenix* was the first successful steamship to be entirely American in origin, but its success was overshadowed by Robert Fulton's *Clermont* (1807), which used an English engine made by James Watt. Since Fulton was allied with Livingston, who still had the monopoly on Hudson River navigation, the Stevenses were forced to send the *Phoenix* to Philadelphia, with Robert on board for the first ocean voyage by a steamboat. Robert designed over 20 steamboats during his lifetime, and each improved upon the previous one. The *Juliana* became the world's first steam ferry (1811), operating between Manhattan and Hoboken, before threats from Fulton and Livingston forced the Stevenses to move the boat to Connecticut. Among Robert's inventions for steamboats and engines were guard beams supported by iron rods, the camboard cutoff, the use of anthracite coal in boilers, the gallows frame, skeleton walking beams, the hog frame, the balance valve, and spring pilings for ferry slips. Robert was also the first to build a pilothouse to protect the boat's operator.

Colonel John Stevens and his sons were also early proponents of railroad transportation. John argued for construction of a steam railroad instead of building the Erie Canal. He and Robert built the first locomotive in the United States (1826) and ran it on a circular track on the family's Hoboken estate to demonstrate the potential of railroads. In 1830, Robert and younger brother Edwin formed the Camden & Amboy Railroad to run between New Jersey and Pennsylvania. While on a trip to England to order rails and acquire the *John Bull* locomotive, Robert designed a new rail system (it became known as the "T rail") that became the standard section on all American railroads. He also invented the cowcatcher to sweep track obstacles aside in front of locomotives. Other railroad innovations by Robert were the hook-headed spike and the "iron tongue" (fish plate), the use of wooden ties with crushed stone ballast for the rail bed, and the double-slide cutoff for locomotives and large engines.

During the War of 1812, John designed a saucer-shaped ironclad ship for harbor defense that would swivel by the use of screw propellers, but it was never built. Robert developed an elongated shell that could be fired from an ordinary cannon and would explode after penetrating its target, which the federal government eagerly bought. In 1841, Robert and Edwin expanded their father's earlier ironclad proposal and sought government funding to build a huge ironclad steam vessel that would be impenetrable "to shot or shell" with all machinery below the waterline and would use screw propellers to pivot quickly in place.

Congress authorized \$250,000 for them to begin building the 410-foot long "Stevens Battery," but construction went on for decades, and the ship was never finished—as more powerful guns and shells were developed, the ironclad's design was continually changed. After Robert's death (April 20, 1856), Edwin offered to complete the Stevens Battery, but the government declined him. During the Civil War, Edwin built a smaller ironclad vessel, the *Naugatuck*, to demonstrate that the initial plan for the Stevens Battery was indeed practicable. Edwin died in 1868 and left the unfinished Stevens Battery to the state of New Jersey along with \$1 million to complete it—but the money ran out, work was suspended, and the unfinished ironclad was eventually sold as scrap in 1880.

Edwin also bequeathed land and funds for the founding of the Stevens Institute of Technology in Hoboken, which developed a school of mechanical engineering.

Strauss, Levi (1829–1902)

Levi Strauss is known today for coming to the California gold rush, failing as a "forty-niner" but succeeding as a shopkeeper, as most of the money was to be made in selling things to miners rather than in being one. In the process, he is said to have invented denim jeans, which are named for him as Levi's. While the first facts are true, the second is only half true. Denim jeans were already worn by many miners, ranchers, and farmers, appreciated for the durability of their fabric over that of linen or cotton clothing. But it was not until Jacob Davis, a Nevada tailor, developed a process for securing the seams and riveting them at the pockets and the base of the button fly that they became ubiquitous.

Strauss was born to a Jewish family in Bavaria in 1829 and emigrated to New York in 1847 at the age of 18. His older brothers had established a dry goods business, and he worked for them, traveling to Kentucky for three years with product to sell. Strauss became an

American citizen in January of 1853 and then moved to San Francisco. With two older brothers and a sister, they established a dry goods store as the city boomed with citizens making money off of the miners.

They opened one store on Sacramento Street in downtown San Francisco and by 1866 opened larger headquarters on Battery Street. Strauss was a well-known community leader when Davis approached him with his new denim sewing techniques in 1872. Davis ran a tailor shop in town, making everything from tents to horse blankets and wagon covers using fabric purchased from Strauss's stores.

Davis could not afford to patent his riveting process, so he asked Strauss if he would pay the fee and share the patent. Being a good judge of ideas and talent, Strauss agreed. Then he brought Davis to San Francisco to oversee the pant manufacturing for his business, Levi Strauss and Company, incorporated by Strauss and his sister's four sons, who ran the day-to-day operations. The company became the first in the United States to manufacture what were generically called "blue jeans" but quickly came to be called Levi's. The two men maintained their working relationship for the rest of their lives, with Strauss dying in 1902 and Davis in 1908.

Jeans, or Levi's, remained a working man's pant for nearly 50 years after their deaths, when teenagers from subsequent eras began to adopt them as daily wear. In the 1950s, they represented poorer subcultures known as "greasers"; in the 1960s, hippies embraced the style, and in the 1970s, punk rockers preferred the predistressed and washed-out looks.

Telegraph

The telegraph, patented by Samuel F. B. Morse in 1840, had an incalculable impact on the developing United States. While its dominance was comparatively

short-lived, the invention and development of the telegraph nevertheless had a tremendous impact on the growth and development of the country in the mid-19th century.

In some ways, Morse was an unlikely father of such an invention. His creativity was unquestionable, but after graduating from Yale College in 1810, he pursued a career in art and became a well-regarded painter. But that artistic bent was complemented by a scientific mind, one that had been transfixed by a series of lectures on electricity that he had attended at Yale. In 1832, that longtime, continuing interest in electricity led him to pursue the idea of an electric telegraph after overhearing a conversation about the newly discovered electromagnet.

Morse believed his idea was an original one, but in fact, the concept had been proposed as early as 1800. Undaunted by the possibility of competitors, though, this artist pursued the project with an impressive determination, constructing his first working model around 1835. Although he continued to pursue his art while also teaching at the University of the City of New York (later New York University), his primary focus was on developing his telegraph. Drawing upon his university connections, he was aided by a colleague, chemist Leonard Gale, and his friend Alfred Vail in the effort to develop the new machine. In 1838, Morse and Vail originated the system of dots and dashes that would become the Morse code, but even with this language in hand, they were unable to convince Congress to undertake the construction of the telegraph line necessary to make the system operational. Rebuffed at home, they turned to Europe for support to construct a telegraph line there, but that effort, too, came to naught.

Discouraged, Gale and Vail abandoned the project, but Morse continued his efforts and in 1840 was awarded the first U.S. patent for it. Finally, in 1843, Congress gave Morse sufficient financial support to construct the nation's first telegraph line—one that went from Baltimore to the nation's capital. Completed in 1844, on May 24, Morse sent the first message—"What hath God wrought"—and ignited a communications revolution. Indeed, limited only by the time involved for the construction of the network, the telegraph transformed communication first along the East Coast and eventually across the nation, and in Europe as well.

Allowing cross-country communication in a manner never before imagined, the telegraph served to connect the nation, breaking down regional barriers and playing a crucial role in the development of an increasingly national identity and character. In facilitating faster and broader communication, the innovation helped erase many of the regional distinctions that had characterized the nation's earliest years. Indeed, the telegraph was without question the single most important means of long-distance communication in the first century of the American republic. Whether it was used to transmit national news or family developments, the telegraph served to shrink the nation at a time when western exploration, the Mexican War, and the California Gold Rush encouraged expansion. Indeed, the role of the telegraph in communication during the Civil War, as well as its role in the actual development of the West, specifically the way it connected the far-flung western areas both with each other and with the more populous eastern cities, represents some of its greatest historical impact.

It also had a major impact on the national economy. In fact, the telegraph grew almost hand in hand with the other commercially critical development of the period—the railroad—and through their parallel development, the 3,000-mile chasm between the East and West Coasts was bridged in a way that fostered the nation's economic, social, and political development to an unimagined degree. That almost partner-like relationship helped set the stage for the nation's emergence as a world economic power.

While it would take longer to have an impact in the West, where the prospect of stringing the lines necessary was a daunting task given the sparse population and the wide spread of settlements, it is arguable that some of its greatest impact was there—at least in the way it both fostered Western growth while preventing newly settled areas from becoming isolated outliers. The surge of settlers who invaded California beginning in 1849 following the Gold Rush created a sense of urgency and quickened the efforts to string the wires needed to connect the farthest western parts of the nation with their eastern counterparts.

Not surprisingly, the telegraph's development in many ways mirrored the country's, with population and technology initially jumping over the plains states to

California and then later moving eastward to meet up with the ever-increasing migration from the east. Indeed, a disparate collection of telegraph lines dotted the West Coast in the decade following the Gold Rush. In short order, California was witness to the creation of a number of short-range lines set up in such a way that ultimately, San Francisco was connected with Sacramento and Stockton and San Jose. Soon afterward, plans were underway to develop a network heading east from California to Nevada. Meanwhile, the late 1850s saw Missouri undertake similar local efforts, and these were eventually coordinated with the existing eastern networks so that cross-country communication from New York and Washington to the outer reaches of the settled west in St. Louis on the Mississippi River was possible. However, with these advances, the question of a transcontinental connection loomed large.

Another outgrowth of the telegraph was the emergence of the government as a vehicle for actively fostering economic progress. Reflective of this phenomenon was the passage in June 1860 of the Pacific Telegraph Act, legislation that authorized the expenditure of almost half a million dollars over 10 years to construct a telegraph line from the western border of Missouri to San Francisco. This effort was motivated at least in part by the growing recognition that the communication afforded by the development of a true transcontinental telegraph network would allow for the development of truly national businesses, as well as for quick commercial transactions between the eastern bankers and western developers whose efforts they were funding.

In addition, the Civil War heightened the existing sense of urgency concerning the development of a widespread telegraph network. The Lincoln administration recognized that in a national war, the telegraph offered a distinctive and never-before-available means of communication, one that could be critically important for coordinating and directing troop movements as well as sharing wartime news. These factors became particularly important as the war dragged on far beyond initial expectations.

The process of growth went forward, and to the astonishment of most observers, results were achieved with almost lightning speed. Setting their first poles in the ground on July 4, 1861, the Western Union Telegraph Company, the major corporate outgrowth and benefactor of the telegraph boom, began the process of

stringing the wires to connect St. Louis with the network that already linked Nevada to San Francisco and other California cities. The efforts to string wires across hundreds of miles of often barren, unoccupied, and unsettled frontier was a truly monumental task, but upon completion, the nation had a wholly functional system (though admittedly rudimentary), one that allowed for the first transcontinental telegraph wire to be sent by California Chief Justice Stephen Field to President Abraham Lincoln on October 24, 1861. While the creation of the network was itself an impressive undertaking, its impact was no less monumental, for in extending the reach of the telegraph, the isolation of the West was markedly reduced, and the enhanced communication—and, in turn, the greater commerce—was no less so in its impact on American society.

While the creation of the transcontinental telegraph network was unparalleled, it was in fact, only a beginning, with work continuing in a determined effort to increase the reach of telegraphic communication. While the same challenges remained, additional poles and wires were installed across new expanses of isolated prairie. It was an arduous task, but progress was made, and as the Transcontinental Railroad developed in the aftermath of the Civil War, the telegraph also grew, in some cases literally, alongside it, all the while expanding its reach throughout the far-flung United States.

For all its early unprecedented and pathbreaking influence, the telegraph's era was comparatively short-lived. In 1876, less than a decade after the Golden Spike was driven, signaling the completion of the Transcontinental Railroad, there came the invention of the telephone, and in comparatively short order, a national telephone network, often using the same poles and wires that had fueled the telegraph, spanned the nation. But while its period of dominance may have been short, the legacy of the telegraph and its multifaceted impact on the United States cannot be overstated.

Primary Document: Act Authorizing Construction of a Transcontinental Telegraph (1855)

In 1855, Congress authorized the construction of a transcontinental telegraph using public lands and private builders. The national telegraph system fundamentally changed communication in America, making it possible to communicate over long distances in a short time.

CHAP. CXII.—An Act authorizing the Construction of Line of Telegraph from the Mississippi or Missouri Rivers to the Pacific Ocean. Right of way Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That Hiram O. Alden . . . James Eddy, their associates and assigns, are hereby authorized and empowered to construct, at their own expense, a line of telegraph, from such point on the Mississippi or Missouri River as they may hereafter select, through the public lands belonging to the United States, over which lands the right of way two hundred feet in width, for that purpose, is hereby granted, to San Francisco, in California, in as direct a line as practicable.

SEC. 2. And be it further enacted, That all voluntary or intentional injuries to said line of telegraph, or to any property thereto belonging, Penalties for injuries to such telegraph, within the territories of the United States, shall be deemed, and are here-by declared to be wilful and malicious trespasses, and shall be punished as such; and all laws of the United States now in force in any territory thereof, or which may hereafter be enacted for the better security and protection of property, and applicable to such offences, shall be, and they are hereby, extended, for the protection of said line of telegraph, into and over all the territory belonging to, and under the jurisdiction of the United States, through which the same may be constructed; and all legal process and proceedings for the detection and punishment of the aforesaid offences shall be within the jurisdiction of the courts, and shall be issued and executed by the proper law officers in the States or organized territories. APPROVED, February 17, 1855

Ten-Hour Movement

The Ten-Hour Movement was a labor reform movement that began in the 1840s, largely by female textile workers in Lowell, Massachusetts, to fight for a shorter workday. In the early 1840s, mill workers typically worked 11 to 13 hours per day. As competition increased and the price of cloth decreased, owners of textile mills looked for ways to maximize profits.

Speed-ups (increasing the speed of machinery to make operatives work faster) and stretch-outs (increasing the number of machines that operatives were expected to tend) were common practices. The premium system was also instituted, in which corporations paid cash bonuses to the overseers whose factories made the largest amounts of product. These practices caused great demands on the mill workers, though they were inconsistent among the many mills within Lowell. The one practice that was consistent was the long workday.

In 1840, U.S. president Martin Van Buren issued an executive order making 10 hours the legal length of the working day, but only for federal workers and those on government contracts, not employees of private corporations. Labor reformers decided to petition for similar working hours at the state level. In 1843, a petition with 1,600 signatures from Lowell, Massachusetts's workers was submitted to the statehouse.

In late 1844, the Lowell Female Labor Reform Association (LFLRA), led by mill worker Sarah Bagley, organized to demand a shorter workday. This was a cause the workers could fight for together as a single unit across all of the different mill corporations regardless of practices or working conditions in the individual mills. At this time, women began to identify themselves as the female working class and were united under the LFLRA motto, "Try again!" The LFLRA argued that the shorter workday would let workers lead healthier and better lives. These

women's actions led them into the political world, where their concerns began to be heard.

The state legislature appointed an investigative committee in 1845 that visited several mills in Lowell and also had several mill workers, including LFLRA president Bagley, testify about their working experiences. At the end of its investigation, the committee reported that the legislature did not have the power to determine hours of work and that the length of the workday must be decided between the corporations and the workers in the textile mills. Because organizers and petition signers were mostly female and committee members believed in the common courtesy idea that men should and would look out for women in the workplace, the report stated, "Operatives should rely on the good will of their employers, rather than on legislative intervention." The committee felt that restricting the workday would affect competition among the mills and wages. Wages, it noted, should be set by the market for the goods as well as negotiated between laborers and owners.

In November 1845, only a few months after the special committee report denied the workers' petition to limit the workday, committee head William Schouler ran for reelection as Lowell's representative to the state legislature. Due to his report, workers in Lowell strongly opposed his election, and he lost. Following his defeat, members of the Lowell Female Labor Reform Association published the following statement in *The Voice of Industry* newspaper:

Resolved, That the members of this Association tender their grateful acknowledgements to the voters of Lowell for consigning William Schouler to the obscurity he so justly deserves,

for treating so unjustly and so ungentlemanly the defense made by the delegates of the Association, by the special committee of the Legislature, to whom was referred petitions for the reduction of the hours of labor, of which he was chairman.

Petitions continued, with women and men workers united in action. The Massachusetts Senate launched another investigation, but this also failed to recommend legislation to shorten the workday. There was a slight reprieve in the long workday in 1847, when the corporations agreed to allow more time for meals. In 1850, a group of Free Soilers, liberal Democrats, and disaffected Whigs pledged to support the 10-hour day and were successfully elected to office. Future Massachusetts governor Benjamin Butler, from Lowell, led this effort, and he and other elected officials tried numerous times to pass legislation. Finally in 1874, a law that applied to only women and child workers was passed to limit the workday to 10 hours. The early 1840s actions of the LFLRA were a significant step toward enacting this critical legislation.

Primary Document: Excerpt from the Preamble and Constitution of the Lowell Female Labor Reform Association (1846)

The Lowell Female Labor Reform Association formed in 1845 to agitate for a 10-hour workday. Before the end of its first year, it had over 500 members. The following is an excerpt from the organization's preamble and constitution, in which the group argues

that its members cannot improve themselves if they do not have a reasonable workday.

Whereas we, the Operatives of Lowell, believing that in the present age of improvement nothing can

escape the searching glances of reform; and when men begin to inquire why the Laborer does not hold that place in the social, moral and intellectual world, which a bountiful Creator designed him to occupy, the reason is obvious. He is a slave to a false and debasing state of society. Our merciful Father in his infinite wisdom surely, has not bestowed all his blessings, both mental and moral on a favored few, on whom also he has showered all of pecuniary gifts. No! to us all has he given minds capable of eternal progression and improvement!

It now only remains for us to throw off the shackles which are binding us in ignorance and servitude and which prevent us from rising to that scale of being for which God designed us.

But how shall this be done? How shall the mass become educated? With the present system of labor it is impossible. There must be reasonable hours for manual labor, and a just portion of time allowed for the cultivation of the mental and moral faculties and no other way can the great work be accomplished.

We know no employment is respectable only as long as these employed are such, and no farther than they are intelligent and moral, can they merit the companionship and esteem of their fellow-beings. It is evident, that with the present system of labor, the minds of the mass must remain uncultivated, their morals unimproved, and our country be flooded with vice and misery!

Shall we, Operatives of America, the land where Democracy claims to be the principle by which we live and by which we are governed, see the evil daily increasing which separates more widely and more effectually the favored few and the unfortunate many, without one exertion to stay the progress?—God forbid! Let the daughters of New England kindle the spark of philanthropy on every heart till its brightness shall fill the whole earth! . . .

Toothpaste

The development of toothpaste represented a major advance in personal hygiene and health care. Beginning as a homemade product made from an unimaginable combination of ingredients, toothpaste has developed into both a multimillion-dollar business as well as an important contributor to better dental health.

There is evidence of a paste being used to clean teeth as long ago as ancient Egyptian times. That version, reportedly composed of powdery substances ranging from crushed bones to burnt eggshells and ashes, appears to be a forerunner of the early 19th-century powders that sometimes included crushed burnt toast and bark as a form of abrasive. Herbal mints were included in an early attempt to make the taste more palatable.

Most early 19th-century powders were literally homemade mixtures, concocted at home based on word-of-mouth recipes. Prior to the development of the paste that emerged in the 1850s, these powders usually included a form of soap for cleaning that was

mixed with a variety of abrasives, the most common of which was a form of chalk. These pre-Civil War toothpastes, more powders than pastes, were replaced in the early 1850s by a new, pastelike product. Sold in a glass jar, “*crème dentifrice*,” as it was called, quickly became popular, changing the nature of tooth care forever.

Commercially, everything changed in 1873 when the Colgate Company, one of the nation’s largest soap and perfume manufacturers, began to mass-produce an actual paste, offering it in the traditional jar. Two decades later, in 1892, Dr. Washington Sheffield first offered toothpaste in a tube, his design being very similar to the modern version. Colgate soon followed suit, offering its market-dominant product in a tube all but indistinguishable from Sheffield’s.

The next major advance in the development of toothpaste came in 1914 when, following studies indicating that it significantly reduced cavities, fluoride was added as a standard ingredient. Around this same time, toothpastes containing reduced abrasives were developed, an advancement aimed at limiting problems stemming from overzealous brushing. Meanwhile, the

In 1880, a London doctor saw a painter using paint from collapsible tubes and borrowed the idea for toothpaste. Before tubes, tooth-cleaning compounds were generally powdered and sold in jars or cans. Colgate & Company began mass-producing toothpaste in tubes in 1896. (History of Advertising Trust/Heritage Images/Getty Images)

post-World War II era witnessed a new focus on ingredients that could help with disease treatment and prevention as well as matters such as tooth sensitivity. Also, newly developed toothpastes often included whitening ingredients. Others offered greater cavity protection while also helping combat plague, gum disease, and bad breath.

The growth of the business side of toothpaste production led to greater external scrutiny, and in 1934, the American Dental Association (ADA) for the first time undertook to rate products, giving an “accepted” label to those that were safe and had a therapeutic effect. The Food and Drug Administration (FDA) soon followed suit, categorizing toothpastes that did not contain fluoride or made no therapeutic claims as cosmetics. The ADA, while acknowledging that it does

not study every product, now recommends one of the five brands to which it has given the “accepted” label: Crest, Colgate with MFP, Aim, Aquafresh, and Macleans with fluoride. These efforts to get people to limit themselves to five acceptable toothpaste options and avoid those that have not been shown to have therapeutic value are a clear reflection of the changed nature and purposes of toothpaste.

Torpedo

Today, a torpedo is an underwater, self-propelled missile fired from either a ship or submarine. Torpedoes are designed to detonate on contact, thus destroying their targets. In the 19th century, the term applied to stationary naval mines. Both the Union and Confederate Navies used early explosive weapons during the Civil War. The spar torpedo, which had an explosive on the end of a long boom triggered either by a spring mechanism or a long pull cord, was used with limited success by submersibles during the war. It was adopted by several navies and used in combat several times over the next few decades.

Early attempts to create underwater explosives were largely unsuccessful. In 1626, Cornelius Drebbel, who was Dutch but worked for the English King James I, attempted to attach underwater explosives to an early submarine. Drebbel put his invention to the test at the Siege of Rochelle as part of the Anglo-French conflict, but the experiment failed to produce

any real explosions. In 1776, the *Turtle*, an American submarine engineered and built by David Bushnell, also attempted torpedo technology by a different means. Bushnell designed the *Turtle*, a one-man submersible vehicle, to affix explosives onto the underwater portion of British ships. This experiment also failed.

Steamboat innovator Robert Fulton also experimented with underwater explosives. In fact, he coined the term "torpedo" in 1800 when he demonstrated his submarine, the *Nautilus*, to English, French, and Dutch investors. Like Bushnell, Fulton hoped to use his submarine to attach explosives to ships. Finding no takers for his ideas, Fulton shifted his attention to developing an exploding missile that would work without a submarine to put it in place. He demonstrated his "infernal machine" in 1805, but the British government declined to purchase the technology, believing it unfair and immoral. Fulton tried again with the U.S. government two years later. During the War of 1812, the U.S. Navy did deploy a torpedo to destroy a British ship, again with no success. The British heard of the attempt on its navy and decried the torpedo as cruel.

The U.S. Navy began producing its own torpedoes in 1885, based on a design conceived by John Howell in 1870. Howell's torpedo used a flywheel to drive its propeller. This simple design was able to go farther and drive straighter than a Whitehead torpedo, redesigned in 1866 by Robert Whitehead from a design conceived by Giovanni Luppis of the Austro-Hungarian Navy. Howell's torpedo was loud and required a steam turbine to impart energy to the flywheel. It was abandoned in favor of the British model. Many other navies developed home-grown alternatives but continued to buy superior Whitehead torpedoes, especially after Whitehead introduced gyroscope-driven models in 1895.

By this time, torpedoes had been used in several battles; their debut in large-scale combat came with the Russo-Japanese War of 1904. Even decades after their introduction, torpedoes remained unreliable weapons—the U.S. Navy did not receive fully tested torpedoes until nearly two years after Pearl Harbor.

After decades of refinement during the submarine patrols of the Cold War, today's torpedoes are

generations beyond their ancestors. They can travel at remarkable speeds, guided either by internal sensors or the ship that launched them via control wires. The Soviet Union deployed torpedoes armed with nuclear warheads, although none were ever fired.

Transatlantic Cable

Transatlantic cables are used to transmit electrical signals under the Atlantic Ocean for telecommunications between continents. Up to 99 percent of all international data travels through undersea cables, making them the most important medium in telecommunications. Data transmitted through transatlantic cables can be over eight times faster than data transmitted via satellites. Undersea cable technology is also comparatively cheaper to implement than that of satellites. The data transmitted through transoceanic cables includes, but is not limited to, text messages, phone calls, and Internet usage. Just as the first transatlantic cables, modern transatlantic cables must address the issue of signal losses during transmission.

The first transatlantic cables had the purpose of implementing telegraphic communications, and they aimed to replace telegrams carried by ship between the United States and Europe. Communication between the two continents could take as long as 10 days before undersea cables became successfully operational. The first cable was laid down by Cyrus West Field and the Atlantic Telegraph Company, between the Irish island of Valentia and the Canadian town of Heart's Content. The cable was ready for use

in 1858, 119 years after the invention of the telegraph by William Cooke and Charles Wheatstone. This achievement also marked the year of the first successful transatlantic telegraphic transmission.

The first official telegraphic exchange between the two continents came on August 16 in the form of a congratulatory message from Queen Victoria of the United Kingdom to the president of the United States, James Buchanan. It read, "Europe and America are united by telegraphy. Glory to God in the highest; on earth, peace and good will toward men." After three weeks of cable operation, chief electrician Edward Orange Wildman Whitehouse attempted to increase the voltage to account for signal losses, leading to cable failure.

Sir James Anderson and his crew on the ship *Great Eastern* attempted to lay down the second transatlantic cable in 1865, starting in the Irish island of Valentia. After about 1,062 miles of cable were laid down under the ocean, the cable snapped at the stern of the ship, halting the mission. A second attempt was successfully made by the *Great Eastern* in the following year. On this journey, the crew also retrieved the lost end of the first cable and reconnected it to its original end. By the end of 1866, North America and Europe had two operating cables for telegraphic communications. Telegrams could be transmitted between North America and Europe at the average rate of 0.1 words per minute and at the cost of 10 dollars per page.

Formerly, undersea cables were made of copper, costing approximately \$1 million per circuit. In 1956, the technology began to be replaced by coaxial cables—ones with inner conductors surrounded by tubular insulating layers that in turn were surrounded by tubular conducting shields. The TAT-1 cable (Transatlantic No. 1) was the first coaxial cable of its generation, implementing the transatlantic telephonic system. Modern undersea cables have replaced coaxial and copper cores with fiber-optic technology. The first fiber-optic transatlantic cable, TAT-8, was laid down in 1988, costing less than \$10,000 per circuit.

Modern transcontinental transatlantic cables commonly lie on the path of the earth's orthodrome, as this constitutes the shortest distance between the cities of New York and London. Originally, cables that followed this path tended to terminate in Ireland on the

eastern side and in Canada on the western side, although modern transatlantic cables have a myriad of landing points. There are hundreds of transatlantic cables currently in operation, and they may be categorized as either domestic or international cables. Domestic transatlantic cables have their landing points in the coast of a single country, while international transatlantic cables connect two or more countries together. Transatlantic cables may be also privately owned by single or several businesses.

There exists growing concern regarding the environmental effect of undersea cables, ranging from the waste produced during the cable lifecycle to the overall impact of undersea cable operation and management on wildlife. Generally, cable routes avoid coral reefs lying on their paths. It is believed that recommendations that undersea cable locations be left undisturbed so as not to damage equipment can have a positive impact on the wildlife living around the cable's path. However, this does not mitigate the negative environmental consequences of the cable itself. Sharks are known to be affected by the presence of undersea cables when they gnaw on them, but the reason for this behavior is not yet clear.

Modern cables contain different layers of material around an optical fiber core, with the purpose of protecting the signal throughout its travel. The signal is also amplified at exact points to account for signal losses with the use of optical communication repeaters and relays. The typical layers of a modern transatlantic cable, from outermost to innermost, consist of: polyethylene, Mylar tape, stranded steel wires, an aluminum water barrier, polycarbonate, copper or aluminum tube, petroleum jelly, and optical fibers.

Advancements in fiber-optic technology, such as research on optical amplifiers, are currently being undertaken to further improve transatlantic cables by reducing latency and increasing signal quality. These efforts reinforce the tendency to maintain undersea cables as the most important medium in telecommunications.

Transverse Shuttle

The transverse shuttle was a lockstitch sewing machine component that drove a bobbin horizontally to create a lockstitch. The design, which exposed the bobbin, closely resembled a boat—and was also known as a “boat” shuttle for this reason. The transverse shuttle became popular in the “New Family” sewing machine sold by the Singer Manufacturing Company in the mid-1800s.

Sewing machine pioneer Elias Howe invented the transverse shuttle. Howe trained as an apprentice in the textile and carding industries from a young age and later learned precise instrumentation as an apprentice in a mechanic's shop. Not only did Howe secure the first U.S. sewing machine patent in 1846 for his lockstitch sewing machine, he also patented the zipper in 1851.

German sewing machine companies continued to use Howe's transverse shuttle design until World War II, when many manufacturers switched to arms production to support the war effort. The bullet-shaped vibrating shuttle, which drove the bobbin in an arc shape, eventually replaced the transverse shuttle.

Twine Knotter

The twine knotter began the agriculture industry's mechanical revolution. The knotter, which binds grain bundles with twine, was developed by John Appleby. Appleby was born in New York in 1840 and moved to Wisconsin as a young adult. At the age of 18, he created a basic knotter, but the farming community was uninterested.

Appleby left his home and inventions to fight in the American Civil War in 1862. Upon returning home in 1865, he continued development of the knotter. He created another knotter that used wire to bind wheat bundles, but small pieces of metal stuck in the grain and hurt the livestock when the feed was ingested.

In 1878, he developed a knotter using a twine binder. Twine was not harmful if cattle ingested it. With the support of the farming community, Appleby patented the idea. The twine knotter was licensed to the Deering Harvester Company and was later used on machines from Cyrus McCormick and Champion Machine. The patent was sold to Champion Machine in 1881. John Appleby continued to invent before he passed away in 1917.

Twist Drill

Born in New Hampshire, mechanic Steven A. Morse patented the twist drill in 1861. Although Morse created the drill to cut metal, it could also cut concrete, plastic, and wood. With a \$30,000 stockholder investment, he opened the Morse Twist Drill and Machine Company in 1864. Although Morse left the company four years later, he acquired several other businesses and continued to manufacture cutting tools.

Morse showcased his twist drill and other tools to the public for the first time in Philadelphia at the 1877

Centennial Exhibition. His businesses continued to flourish well into the 20th century. During World War II, Morse's companies grew nearly 500 percent as a result of increased output as part of the war effort.

Steven A. Morse's twist drill has left a legacy. His twist drill bits have become the most common type of drill bit produced today. The twist drill bit's popularity is attributed to its low manufacturing costs as well as its many uses. Since the invention of the twist drill bit, Morse's companies have produced over 25,000 types of cutting tools, with uses from construction to orthopedic surgery.

United States Capitol Building, Construction of

The project to build the United States Capitol Building was begun by President George Washington (1732–1799). Construction of the building took many years as builders periodically expanded on the original design. In addition, fire damage during a war, a need for expansion, and dilapidation brought on by age necessitated several reconstructions, additions, and restorations. Since its inception, the grandeur of the Capitol Building had been the product of artists who had added their impressive works of art and innovative builders who had expanded the structure.

The first capitol of the United States was established in Philadelphia. However, during Washington's presidency, plans were made to construct a new capitol in Washington, D.C. Consulting with French engineer Major Pierre L'Enfant, Washington chose the exact site for the construction of the Capitol building. In 1792, Washington held a competition between architects to see who could come up with the best design. After judging William Thornton's as the best, Washington set the cornerstone for the Capitol (with

Masonic rites) in 1793. Construction continued long after Washington retired.

As the nation grew and the number of its representatives in government increased, assemblies outgrew their respective chambers. Consequently, old chambers were reassigned and new chambers were built. For example, the Old Senate Chamber (the first chamber to be completed in 1800) served as a meeting place for the U.S. Senate from 1819 to 1859. After the Senate outgrew it, the U.S. Supreme Court used it from 1860 to 1935. Since that time, the chamber has served as a legislative history museum. At one point, the Capitol building housed the Library of Congress, but the need for more space led to the library's move to three nearby buildings.

During the War of 1812 (1812–1815), British troops set fire to several buildings in Washington, D.C., including the Capitol building. With only the exterior walls left intact after the fire was extinguished by a rain storm, the building was reconstructed in 1827 with a low, wooden dome design. In the late 1850s, new wings were added, which more than doubled the size of building. The expansion gave architects an opportunity to suggest a much larger dome design, because they believed that the old dome no longer suited the larger building's proportions. Congress approved the construction of the new fireproof, cast-iron dome. The cost of the new dome was \$1,047,291 (\$232 million 2015 dollars). It was constructed with 8,909,200 pounds of ironwork bolted together in a way to make it look like the stone in the building.

In 1856, the old dome was removed, and 5 million pounds of new masonry were placed on the existing walls to serve as a foundation for the new dome—which was lifted into place by several steam-powered derricks. Construction of the new dome was still underway during the American Civil War (1861–1865). Some politicians advised President Abraham Lincoln (1809–1865) to halt the costly construction so that the money could be used for the war effort. Lincoln rejected their advice. He explained, “If the people see the Capitol going on, it is a sign that we intend the Union to go on.” Philip Reid, a slave, oversaw the casting of the *Freedom* statue that was mounted on the exterior zenith of the completed dome in 1863.

Besides the dome itself, perhaps the other most impressive architectural achievement of the Capitol building is the rotunda (a circular room 96 feet in diameter and 180 feet in height) under the dome. The rotunda serves as the principal circulation space in the building by connecting all of the major chambers. Throughout the years, the rotunda has been used for important events and ceremonies, including the lying in state of eminent citizens. The rotunda contains statues on the ground level and paintings throughout. *The Apotheosis of Washington*, for example, is a 4,664 square-foot fresco by Constantino Brumidi on the interior high point of the dome. Brumidi's painting contains figures as much as 15 feet high that can be seen in detail from 180 feet below. Washington, the main figure of the painting, is shown rising to heaven surrounded by the personifications of Liberty, Victory, and Fame and by 13 maidens who symbolize the original 13 states.

Besides the new chambers for the Senate and the House of Representatives, other chambers included the Senate Committee Room and the House Committee Room. The building also included the President's Room, which provided a place for the president to stay when he visited the Capitol building, and the National Statuary Hall Collection, which was made up of statues donated by individual states to honor notable people from their respective histories.

In the 1950s, a new front marble façade was added to the five-story Capitol building as well as 102 new rooms (adding about 100,000 square feet) at a cost of \$11.4 million. In 2000, a visitor center was added. By 2008, the Capitol building was 751 feet, four inches long by 350 feet wide, and it contained 16 acres of floor space. At its tallest point (at the tip of the *Freedom* statue), it measured 287 feet, five inches. It includes many rooms besides assembly chambers, including offices, restaurants, and repair shops. There are also tunnels and subway links between the Capitol building and nearby Senate and House office buildings. Instead of being a single building, the Capitol building has been transformed into a cluster of connected buildings.

In 2013, Congress approved another major renovation of the Capitol building. The \$60 million, three-year project focused primarily on repairing 1,300

cracks in the cast-iron dome. In 2017, the Capitol building held the distinction of having the tallest cast-iron dome in the world.

U.S. Sanitary Commission (USSC)

The U.S. Sanitary Commission (USSC) was formed in 1861, chiefly to address the health needs of Union soldiers during the Civil War. Thousands of female volunteers raised millions of dollars at “sanitary fairs,” worked as nurses near battlefields, ran army kitchens, and provided housing for disabled or traveling soldiers. This experience of profoundly meaningful service to a nation in crisis positioned some American women to become further engaged in political culture and reform movements.

Henry Whitney Bellows established the Sanitary Commission in June 1861, only weeks after the Civil War (1861–1865) began. Bellows had already helped form the Women’s Central Relief Association but designed the U.S. Sanitary Commission as a more centralized network of wartime volunteers and resources. The USSC was the only private or civilian-run assistance organization recognized by the federal government. In the work of the fledgling Sanitary Commission, Bellows was joined by other notable reformers of the era, including figures such as Frederic Law Olmstead and George Templeton Strong. Louisa May Alcott also threw her support behind the USSC.

Although men controlled the agency at the executive level, women led many commission branches and local affiliates. These Sanitary Commission women delivered direct aid to war casualties, sometimes seeing action at the battlefield. Most women contributed their time and energies as volunteers, while others contributed funding. Over time, some of the women secured state-level jobs as agents of the Sanitary Commission. Through these activities, numerous women emerged as skilled leaders, including Mary Livermore, Abby May, and Louisa Lee Schuyler. Likely the best-known example is Clara Barton, founder of the American Red Cross. In addition, the women of the Sanitary Commission received support from established female leaders in 19th-century American public health such as Dr. Elizabeth Blackwell and Dorothea Dix.

Representatives of the Sanitary Commission stepped in to attend to needs where the Medical Corps of the U.S. Army did not. Nurses were in short supply in the army and were always men, many of whom had little or no training. The USSC trained some women to act as battlefield nurses. The hazards of Civil War combat became so considerable that, before entering battle, soldiers began pinning notes to their uniforms so that in the event of their deaths, their bodies might be easily identified and returned to their loved ones. USSC nurses kept track of these notes and notified families via letters.

Through the labors of the Sanitary Commission, the United States managed to realize alternatives to prior practice regarding the conduct of the war, particularly in relation to soldiers’ needs. With enhanced services, the Sanitary Commission took a more humane approach to the welfare of soldiers, making every attempt to save the lives and, where possible, restore the health of men felled in combat.

The female volunteers of the U.S. Sanitary Commission are remembered for their resourceful approach to patient care, often with quite limited settings and materials. Throughout the war, women improvised environments and supplies for the medical treatment of soldiers. Private homes and public buildings were repurposed as hospitals, particularly in communities that did not already offer medical facilities. Local soldiers’ aid societies often partnered to deliver such services.

As the organization's name implies, the Sanitary Commission's women helped advocate for more hygienic conditions for the treatment of soldiers' injuries and illnesses, following the practices of Florence Nightingale and her Nightingale plan. Part of the Commission's charge was to reduce preventable disease through proper medical precautions and strict standards of cleanliness. The group's members inspected health care facilities and advised on strategies to avoid dietary ailments such as scurvy.

The women of the Sanitary Commission did not confine their activities to emergency medical care. They raised capital to furnish equipment and supplies that soldiers lacked. They searched for missing warriors and those being held as prisoners of war. They contacted families to notify them of the status of their soldiers. When soldiers recovered, Sanitary Commission women worked to help their families reunite and adjust to the changes sustained by soldiers. When soldiers perished, the women were on hand for the burials to acknowledge losses and support mourners.

Women associated with the Sanitary Commission also worked to effect changes in both policy and procedure. For instance, they struggled to remove bureaucratic barriers to the delivery of war relief. They also functioned as champions for the advancement of women. Among their victories in this regard was the securing of pensions for war nurses.

The Sanitary Commission helped mobilize a citizen army during the Civil War. Through their many accomplishments, the workers of the U.S. Sanitary Commission helped the American public understand that women possessed the fortitude and acumen to endure both war and its aftermath. They also demonstrated that local efforts at benevolence and advocacy gained strength through cooperation and coordination via an entity such as the Sanitary Commission. The year after the war, the USSC worked with soldiers, helping them get access to their pensions and back pay. When the USSC disbanded in 1866, women volunteers had raised over \$25 million for its work.

Not all Sanitary Commission women continued in their role as reformers after the Civil War ended, but women who contributed their services to the Sanitary Commission went on to participate in other efforts

intended for the betterment of society, such as the Woman's Christian Temperance (WCTU). They lent their skills and knowledge to social initiatives, ranging from women's suffrage to asylum reform.

Vulcanization

Vulcanization is a chemical process that strengthens natural rubber. It is named for the Roman god of fire, Vulcan, because heat is the secret to the procedure. Charles Goodyear (1800–1860) developed the process.

Goodyear was born in Connecticut. He worked with his father until their hardware business went bankrupt in 1830. He was a self-taught chemist who began experimenting with rubber in 1834. Natural rubber is sticky and soft. It is resilient and waterproof, but its softness limits its uses.

Goodyear began experimenting with rubber to use as a waterproofing material. He contracted with the U.S. government to waterproof mail carriers' bags in 1837. While rubber does repel water, it gets even softer and stickier in hot temperatures and stiff in cold temperatures. The mailbag treatment failed at high temperatures.

Others at the time were experimenting with strengthening rubber by adding sulfur. Goodyear worked with a man who used to work at a rubber factory, and they discovered that when sulfur was combined with rubber, it

did become more durable and less sticky. Goodyear parted ways with the man and continued to work on his own. He discovered that rubber mixed with sulfur reacted when it was dropped onto a hot stove. He heated the rubber to higher temperatures than others had tried. The rubber became drier but was still elastic. It did not lose its flexibility when cold or its dryness when wet. He named the process “vulcanization.”

Goodyear patented the process in 1844. He combined white lead and sulfur with the rubber. Twenty-five parts rubber, five parts sulfur, and seven parts white lead were heated to temperatures over 200°F. The heat did not destroy the rubber. When this product was applied to fabric or leather and heated, the excess peeled off the fabric. The fabric was stronger and repelled water. Goodyear published *Gum-Elastic and Its Varieties* between 1853 and 1855.

Unfortunately for Goodyear, his process was easy to copy. He had many court battles defending his patent in the United States and Europe. He had to borrow money. More legal disputes and factory problems increased Goodyear’s money problems. He died in 1860 owing thousands of dollars to debtors.

Today, vulcanized rubber is used in a variety of products from tires, hoses, and shoe soles to hard, vulcanized bowling balls.

Walker, Mary (1832–1919)

A surgeon for the Union during the Civil War and the only woman to receive the Congressional Medal of Honor, Mary Edwards Walker was born November 26,

1832, in Oswego Town, New York. Her parents, Vesta Whitcomb and Alvah Walker, held 25 acres of land on which they grew fruits and vegetables for market. The family also kept a library for all five of their daughters to use. As a youth, Walker was interested in Spiritualism and supported abolition, temperance, and women’s rights, including suffrage.

Her parents established a school, which their daughters attended. As a teen, Walker began reading her father’s medical books, which he had amassed in search of robust health. Walker took up teaching as a way of saving money for medical school. In 1853, she enrolled in Syracuse Medical College in Syracuse, New York, one of the few coeducational medical schools in the United States, receiving her MD in 1855. That November, she married former classmate Albert Miller, and the two established a joint medical practice.

In the 1850s, Walker gained renown as a writer of both poetry and prose. Much of her prose focused on the idea that women should wear comfortable clothes. Like French novelist George Sand, Walker wore pants in public for comfort. Walker prided herself for being arrested numerous times for wearing a suit, bow tie, and top hat in public.

Due to Miller’s numerous affairs, Walker left him and established her own medical practice. Although male physicians and army officers discouraged her, Walker volunteered as a surgeon in the Union Army in Washington, D.C., at the start of the Civil War. At first she received no pay, but by 1864, she was named an acting assistant surgeon and assigned to the 52nd Ohio Volunteers at a salary of \$80 a month.

During the course of her work, she met prominent people like reformer Dorothea Dix. Walker received periodic leaves to lecture about her treatment of wounded soldiers. She treated them at several of the major battlefields of the Civil War. At the invitation of Union general Ambrose Burnside, Walker served at Fredericksburg, where she met Walt Whitman.

Walker traveled throughout the front with little regard for safety, and in April 1864, Confederate troops captured and imprisoned her for spying. Four months later, the Confederacy traded Walker in a prisoner exchange. President Abraham Lincoln called Walker to the White House to inquire about her

treatment in captivity. Having served under such dangerous conditions, Walker asked the Union Army for pay and a commission in the army. She received more than \$400 in back pay but no commission; the army was still a man's sphere. At war's end, President Andrew Johnson awarded Walker the Medal of Honor, making her the most highly decorated woman in the Civil War. She was then the most famous woman physician in the United States.

Having seen carnage, Walker had difficulty readjusting to civilian life. In 1866, the Social Science Congress invited Walker to Britain, where she lectured to large crowds on topics ranging from wartime service to suffrage to dress reform. She was elected president of the National Dress Reform Association in 1866.

Returning to the United States, she mounted a nationwide lecture tour in 1869, campaigning zealously for women's rights. To further the cause, Walker ran for Congress in 1890 and later for U.S. Senate, though she did not win either election. Though she wrote books about women's rights and attended suffrage conventions, she disagreed with Susan B. Anthony and Elizabeth Cady Stanton, leaders of the movement, on how suffrage ought to be achieved. Anthony and Stanton were demonstrating for a constitutional amendment; Walker, however, felt that the Constitution already granted women the right to vote as citizens and Congress only need enact enabling legislation.

In 1917, Congress revised the Medal of Honor standards to include only "actual combat with an enemy" and took Walker's Congressional Medal, along with the medals of 910 others, away. In 1977, President Jimmy Carter had it reinstated.

Walker died on February 22, 1919, in Oswego Town, one year before women gained the right to vote through the ratification of the 19th Amendment.

Abolitionist, women's rights activist, and Civil War surgeon Mary Walker is the only woman to have ever been awarded the Medal of Honor, the United States's highest military award. Walker was arrested several times for dressing in men's clothing, though she always said she wasn't wearing men's clothes, but "my own clothes." (National Library of Medicine)

Western Union Telegraph Company

The telegraph had been evolving since the 1830s; it was the confluence of many electromagnetic experiments and inventions. In England, William Cooke and Charles Wheatstone constructed a one-mile telegraph line in 1837. The first practical telegraph was demonstrated at the Great Exhibition of 1851 in London. Its earliest use was to carry news of events. At about the same time in the United States, Samuel Morse was developing an improved telegraph using the new electromagnets of Joseph Henry. Morse added battery relays to greatly increase the distance of the Cooke and Wheatstone system. Just as important was Morse's addition of a binary code using dots and dashes to spell out words. The dots and dashes were audio signals using a sound key to produce a "click." By 1840, Morse's system had a 10-mile range. Congress had originally funded the first telegraph line between Baltimore and Washington, D.C., in 1843 in hopes of combining it into the postal system. Congress appropriated \$30,000 for the construction of a 38-mile line along the Baltimore and Ohio Railroad. Congress, however, refused further funding for the telegraph postal service and purchase of the patent rights from Morse. This opened the technology to the private sector. Morse formed the Magnetic Telegraph Company of 1845. Morse built a highly profitable line connecting Washington, D.C., and New York with the help of Ezra Cornell. Cornell (founder of Cornell University) was the inventor of the trench digger. The Magnetic Telegraph Company had started to use underground cable but soon switched to poles to save money and speed up construction. Even though underground cable had failed, Cornell proved the better manager and took over the company.

Additional private companies extended lines to Pittsburgh, Cincinnati, and Louisville. The Morse patents licensed most of the small companies. The newspapers were the first to make the telegraph profitable and caused its rapid expansion. In 1847, the battles of the Mexican-American War were transmitted to waiting reporters across the nation. President James K. Polk's State of the Nation address was carried directly via telegraph in 1848. In Europe, Reuters News used carrier pigeons to carry financial messages between telegraph lines and expand across Europe. In America, the

parent company of Western Union would be the New York & Mississippi Printing Telegraph Company, created in 1851. The name comes from the fact that the first telegraphs printed the Morse code on paper, but the audio system was quickly accepted. A good operator could send 8 to 10 words a minute. The company started to buy out and merge with smaller companies with a vision of creating a fully integrated national service.

The telegraph spread as competing companies set up their own lines. Two major East Coast companies were the New York & Mississippi Printing Telegraph Company of Hiram Sibley and the New York & Western Union Telegraph Company of Cornell. Sibley decided that it was cheaper to buy up smaller companies than to build new lines. This type of business model would be repeated by railroads, telephone companies, and, more recently, cell phone companies. Sibley also decided to standardize all service on the use of the Morse code. The spread of the telegraph augured the business model of the telephone and cell phone markets. The larger companies soon realized the advantages of merging to build even larger markets and gain economies of scale and effort. To that end, the East Coast competitors merged in 1855 to form the Western Union Telegraph Company. The next phase of innovation was, as for all inventions, cost reduction. The major cost of the telegraph was in the iron wire connections on miles of poles, which inspired cost-saving inventions. J. B. Stearns invented a relay sensing system in 1858 that allowed two messages, one in each direction, over a single wire.

As railroads expanded, the use of the telegraph avoided railroad crashes and facilitated switching on the then one-way tracks. The railroad right-of-ways also provided land for the spread of the telegraph. Business created demand for the telegraph as well. Businessmen could now be connected to the markets in New York and their operations in other cities. Bankers were also early adopters of the telegraph. Initially, telegraphs were at rail stations in major cities. Once an operator decoded a message, boys then ran the messages to business offices. Many famous businessmen and inventors, such as Andrew Carnegie and Thomas Edison, started as telegraph operators and messengers. The Civil War created even more demand for the telegraph. President Abraham Lincoln used it to send his

1860 call for troops to governors. During the war, Lincoln was like a teenager with a cell phone, hanging out at the White House telegraph station for news of the war. Union generals quickly adopted the telegraph as a means of communication. During the Civil War, an estimated 6 million messages were sent using 1,500 telegraph operators. The first transcontinental telegraph system was established in 1861 by connecting smaller services across the West to a line through Alaska to Moscow. The transcontinental line was sponsored and funded by the U.S. Congress because no company had the necessary funds for such a large project. Western Union did win the bid to build it. By the end of the war, there were over 200,000 miles of telegraph in operation.

In 1866, Western Union completed the first stock ticker service, which proved to be a highly profitable business. The first successful transatlantic telegraph cable was completed on July 27, 1866. In 1871, Western Union continued its horizontal integration with new businesses with a money transfer service. Now banks could “wire” funds across the country rapidly. In 1884, Western Union became one of the 11 original American companies to be tracked in the Dow Jones stock average. Eventually, Western Union absorbed over 500 companies to become a major corporate giant by 1890. In the 1870s, Western Union tried to defend itself against the telephone by entering the business, hoping to utilize its wired infrastructure. Alexander Bell’s patent challenges prevented Western Union from entering the telephone business, however. As the telephone took over, Western Union focused on its money transfer business. Western Union was considered one of the first industrialized monopolies and was able to merge into the telephone business, which was also dependent on electrical wires. In 1908, Western Union was briefly absorbed into the American Telephone and Telegraph Company (AT&T). The government would use antitrust laws to force the two to separate.

Zipper

Tied ribbons, buttons, hooks and eyes, and snaps were earlier ways to fasten things together until the invention of the zipper, credited to several different men over a span of years.

In 1851, Elias Howe, who had previously invented the sewing machine, received a patent for what he called an “Automatic, Continuous Clothing Closure.” Too busy promoting the sewing machine, he ignored his own new invention. In 1893, Whitcomb Judson designed a fastener for shoes that he called the “Clasp Locker,” and he started the Universal Fastener Company to facilitate mass production. The product debuted at the 1893 World’s Fair in Chicago, but customers did not flock to it.

Gideon Sundback, Judson’s employee at the Universal Fastener Company, received a patent for his version, the “Separable Fastener,” in 1917. His improvements to earlier designs included two rows of interlocking teeth that latched together with the help of a slider, the most similar design to what is used in the current day.

Finally, the B. F. Goodrich Company used Sundback’s device as a fastener on a new type of rubber boots and was the first to call the device a “zipper.” Early on, zippers were mainly used on boots and tobacco pouches, but within 20 years, the fashion industry began to use zippers on clothing, particularly to replace the buttons on men’s trousers.

 - biographical details, 1:111
 - first successful steam-powered boat developed by, 1:111–112, 115, 151
 - monopoly granted to, 1:111–112, 136, 293
- Fitzroy, Nancy DeLoye, 1:78
- Flatboat, 1:112–114
- Flexible catheter, 1:22–23

- Floating dry dock (1849), 1:228–230
 primary document: excerpt from Abraham Lincoln's patent application for the floating dry dock (1849), 1:229–230
- Floppy disk, 3:197–198
- FM radio, 2:272–273
- Folding cabinet bed, 2:68–70
 primary document: patent for folding cabinet bed (1885), 2:69–70
- Folger, Timothy, 1:96–97
- Folsom, Joseph Libbey, 1:172
- Food and Drug Administration (FDA), 3:172
 and AIDS research, 3:172, 239
 and artificial sweeteners, 2:137; 3:18–19
 and birth control, 3:32, 307
 on cosmetic surgery, 3:249
 creation of, 2:172
 first female lab chief, 2:232
 and genetically modified foods, 3:272
 primary document: letter on regulation of robotic surgery (2013), 3:230–232
 and robotic surgery, 3:229, 230, 250
 and toothpaste categorization, 1:300
- Food preservation, 2:70–71
- Food production, Native American, 1:23–25
- Ford, Henry (1863–1947), 2:36, 40, 202–204
 and assembly line, 2:170, 179–181
 biographical details, 2:202–203
 and Edison, Thomas, 2:59, 203
 “Fordism,” 2:204
 Model A, 2:181, 203–204
 Model T, 2:170, 180, 182, 203–204
- Fortran, 3:56–57, 69, 121, 155
- Fossey, Dian (1932–1985), 3:198–199
- Fountain pen, 2:71–72
- Franklin, Benjamin (1706–1790), 1:4, 25–27
 American Philosophical Society created by, 1:4, 71–72
 electricity experiments, 1:4
 glass armonica invented by, 1:4, 31, 32
 primary document: letter describing experiments with electricity (c. 1750), 1:26–27
- Franklin, James, 1:11, 25
- Franklin stove, 1:27–31
 primary document: Excerpt from *An Account of the New Invented Pennsylvanian Fire-Places* (1744), 1:28–31
- Frasch process, 2:72–72
- Freeze-dried food, 2:273
- Freireich, Emil Jay, 3:261
- French and Indian War (1754–1763), 1:3, 35, 208
- Freon, 2:204–205, 215, 220, 311; 3:38, 192
- Frick, Henry Clay, 2:35
 primary document: correspondence with Andrew Carnegie regarding Homestead Strike (1892), 2:37
- Fugitive Slave Act (“Compromise of 1850”), 1:172
- Fuller, Richard Buckminster (1895–1983), 3:57–58
 primary document: drawing of R. Buckminster Fuller's Geodesic Dome (c. 1933), 3:58
- Fulton, Robert (1765–1815), 1:114–115
- Gaffer tape, 1:175. *See also* Adhesive tape
- Gagarin, Yuri, 3:4, 237
- Gallo, Robert, 3:172, 175
- Galvin, Joseph, 2:205
- Galvin, Paul Vincent (1895–1959), 2:205–206
 biographical details, 2:205
 mass production process of automotive radios created by, 2:205–206
 Motorola cofounded by, 2:182
 and Motorola 5T71 radio, 2:205–206
- Garbage disposal, 2:273–274
- Gas mask, 2:274
- Gas transmission, 2:73–74
- Gas tungsten arc welding, 1:115–116
- Gas well, 1:230
- Gates, Bill (1955–), 3:163, 199–201, 244
 on artificial intelligence, 3:183, 191
 Bill & Melinda Gates Foundation, 3:212, 199, 201, 270
 cofounder of Microsoft, 3:190, 199–201, 217, 218
 and Jobs, Steve, 3:211, 212
- Gatling, Richard, 1:174, 247–248
- Gene patenting, 3:270–271
- General Electric, 2:74–75
- General Motors (GM), 2:206–207
- Genetic engineering, 3:201–204
- Genetically modified foods, 3:271–273
- Geographic Information Systems (GIS), 3:164
- Gibbs, Mifflin Wistar, 1:173
- Gilbreth, Lillian (1878–1972), 2:208
- Gilleland, John, 1:185
- Gilpin, Thomas, 1:266
- Glass harmonica (Armonica), 1:30–32
 primary document: excerpt of Benjamin Franklin's letter describing the glass harmonica (1762), 1:32
- Glenn, John
 first manned satellite (Friendship 7) piloted by, 3:95
 Mercury 7 crew member, 3:88, 95
 oldest human to fly in space, 3:238
- Glenn, William, 3:180
- Glennan, Keith, 3:98, 137
- Glidden, Carlos, 2:155
- Glidden, Joseph F., 2:19–23
- Gliders, 2:165, 176–177
- Global Positioning System (GPS), 3:59–60
- Glover, Elizabeth (d. 1643), 1:32–33
- Goddard, Robert H., 2:312
- Godfrey, Thomas (1704–1749), 1:33–34
- Goeppert-Mayer, Maria (1906–1972), 3:60–61
- Gold-mining technologies, 1:231–232

- Golden Gate Bridge, 2:274–276
 primary document: letter of Charles Ellis to the *San Francisco Chronicle* (1930), 2:275–276
- Goldmann, Felix, 2:19
- Goldsmiths, 1:36, 180, 267. *See also* Iron- and silversmithing

Contents

VOLUME 1: COLONIAL AMERICA TO 1865

Introduction, xxi

Chronology, xxvii

Section 1: Colonial America and Enlightenment Science, 1

Overview, 1

American Philosophical Society, 8

Primary Document: Memorial of the American Philosophical Society Favoring an Exploration of the Alaskan Coast (1868), 10

Astronomical Almanacs, 11

Primary Document: Aphorisms from *Poor Richard's Almanack* (1732–1758), 13

Banneker, Benjamin (1731–1806), 13

Primary Document: Letter of Thomas Jefferson to Benjamin Banneker, Expressing Jefferson's Belief That Blacks Had Talents Equal to Other Races (1791), 14

Primary Document: Frontispiece of Benjamin Banneker's *Pennsylvania, Delaware, Maryland and Virginia Almanack and Ephemeris* (1792), 15

Bifocals, 16

Primary Document: Benjamin Franklin's Letter Describing His Invention of Bifocals (1725), 17

Bushnell, David (1740–c. 1824), 17

Primary Document: Engraving of David Bushnell's *American Turtle* (1775), 18

Colden, Jane (1724–1766), 19

Daylight Saving Time, 20

Extension Arm (Long Arm), 21

Fire Safety, 21

Flexible Catheter, 22

Food Production, Native American, 23

Franklin, Benjamin (1706–1790), 25

Primary Document: Letter of Benjamin Franklin Describing His Experiments with Electricity (c. 1750), 26

Franklin Stove, 27

Primary Document: Excerpt from Benjamin Franklin's *An Account of the New Invented Pennsylvanian Fire-Places* (1744), 28

Glass Harmonica (Armonica), 30

Primary Document: Excerpt of Benjamin Franklin's Letter to Father Giambatista Beccaria Describing the Glass Harmonica (1762), 32

Glover, Elizabeth (d. 1643), 32

Godfrey, Thomas (1704–1749), 33

Iron- and Silversmithing, 34

Kentucky Long Rifle, 35

Lightning Rod, 36

Primary Document: Frontispiece and Title Page of Benjamin Franklin’s *Experiments and Observations on Electricity* (1774), 37

Loom, 38

Primary Document: Excerpts from the Diary of Martha Ballard Describing Home Weaving (1787), 39

Lucas, Eliza (1722–1793), 40

Primary Document: Letter of Eliza Lucas to Her Father (1741), 41

Masters, Sybilla (c. 1675–1720), 42

Mather, Cotton (1663–1728), 43

Natural History, 44

Onesimus (fl. 1706–1716), 46

Peale, Charles Willson (1741–1827), 47

Primary Document: Letter of Charles Willson Peale to Thomas Jefferson Regarding New Agricultural Inventions and Innovations (1815), 48

Priestley, Joseph (1733–1804), 51

Rittenhouse, David (1732–1796), 52

Primary Document: Letter of Thomas Jefferson to David Rittenhouse (1778), 53

“Saugus Pot,” 54

Schooner, 55

Smallpox Inoculation, 56

Primary Document: George Washington’s Order for All Soldiers to Receive a Smallpox Inoculation (1778) and Letter of Edward Rowse to Thomas Jefferson Suggesting the Possibility of Vaccines for Other Diseases (1805), 58

Spinning Wheel, 59

Primary Document: An “Address to the Ladies” Urging American Women to Boycott British Goods (1767), 61

Street Lighting, 62

Swim Fins, 62

Three-Wheel Clock, 63

Primary Document: James Ferguson’s Description of Benjamin Franklin’s Three-Wheel Clock (1773), 64

Turtle Submarine, 65

Primary Document: Letter of David Bushnell to Thomas Jefferson Regarding Bushnell’s Experiments with Submarines (1787), 66

Whiton, David Erskine (1825–1904), 67

Winthrop, John (1714–1779), 68

Primary Document: John Winthrop Describes His Observation of the Planet Venus (1761), 69

Section 2: The New Republic and the Market Economy (1780–1820), 71

Overview, 71

Amphibious Steam Vehicle, 79

Primary Document: Image of an Amphibious Steam Vehicle (1834), 81

Apple Parers, 82

Primary Document: Apple Parer Patent Document Image (1836), 83

Babbitt, Sarah “Tabitha” (1779–1853), 84

Ballard, Martha (1735–1812), 84

Banjo Clock, 87

Blackwell, Elizabeth (1821–1910), 87

Primary Document: Excerpts from “Address on the Medical Education of Women” by Elizabeth and Emily Blackwell (1863), 89

Burr Truss Bridge, 91

Canals, 92

Canning Factory, 95

Charting the Gulf Stream, 96

Circular Saw, 97

Coffee Percolator, 98

- Cotton Gin, 99
- Cotton Sewing Thread, 101
- Dental Floss, 102
- Diffraction Grating, 103
- Erie Canal, 104
 - Primary Document: Letter of Robert Fulton to George Washington Urging Him to Support the Construction of Canals (1797), 106
- Evans, Oliver (1755–1819), 107
 - Primary Document: Letters from Oliver Evans to Thomas Jefferson (1804, 1808), 108
- Fire Hydrant, 109
 - Primary Document: Account of the Detroit Fire (1805), 110
- Fitch, John (1743–1798), 111
- Flatboat, 112
- Fulton, Robert (1765–1815), 114
- Gas Tungsten Arc Welding, 115
- Greene, Catharine Littlefield (1755–1814), 116
- High-Pressure Steam Engine, 117
- Interchangeable Parts, 118
- Internal Combustion Engine, 119
- Jefferson, Thomas (1743–1826), 121
- Lewis and Clark Expedition (1804–1806), 123
 - Primary Document: Excerpts from the Journal of the Lewis and Clark Expedition (1805, 1806), 126
- Lobster Trap, 127
- Lowell Mill System, 128
 - Primary Document: Description of the Life of a Mill Girl from the Lowell Offering (1845), 129
- Milling Machine, 130
- Morey, Samuel (1762–1843), 131
- Multitubular Boiler, 132
- National Road, 132
- Odometer, 135
- Patent and Copyright Statutes, 135
- Practical Ocean Navigation, 137
- Report on Manufactures* (1791), 138
- River Steamer, 139
- Rumford Fireplace, 141
- Rush, Benjamin (1746–1813), 142
 - Primary Document: Excerpt from the Medical Writings of Benjamin Rush (1805), 144
- Screw-Cutting Lathe, 145
- Slater, Samuel (1768–1835), 146
- Steam Engine, 148
- Steam Tractor, 149
- Steamboat, 150
 - Primary Document: Newspaper Announcement of Robert Fulton’s Steamboat (1807) and Charles Dickens’s Account of His Ride on an American Steamboat (1842), 153
- Submarine, 154
- Suspension Bridge, 155
- Swivel Chair, 157
- Thompson, Benjamin (Count Rumford) (1753–1814), 158
- Three-Piece Iron Plow, 159
 - Primary Document: Petition to Congress Asking for a Renewal of the Patent on Jethro Wood’s Cast-Iron Plow (1846), 160
- Vapor-Compression Refrigerator, 161
- Waltham-Lowell Textile System, 161
- Wheel Cipher, 162
 - Primary Document: Excerpts from Thomas Jefferson’s Notes on the Wheel Cipher (Undated), 163
- Whitney, Eli (1765–1825), 163
 - Primary Document: Letter of Eli Whitney to His Father Regarding the Ginning of Cotton (1793), 165

Section 3: Antebellum Industrialization and the Civil War (1820–1865), 167

Overview, 167

Adhesive Tape, 174

Agassiz, Louis (1807–1873), 175

Primary Document: Excerpt from the Journal of Louis Agassiz Describing a Trip to the United States (1846), 176

Anesthesia, 178

Ball Bearings and Babbitt Metal, 179

Best Friend Steam Engine, 181

Breast Pump, 182

Brown Truss, 182

Burglar Alarm, 183

Calliope (Steam Organ), 183

Cannon, Double-Barrel, 185

Primary Document: Excerpt from the Memoirs of Former Confederate General Edward Porter Alexander on “Artillery Hell” at Antietam (1907), 186

Civil War Medicine (1861–1865), 186

Primary Document: Report of Medical Director Robert Murray on Union Casualties Suffered at the Battle of Shiloh (1862), 188

Civil War Nursing, 190

Primary Document: Clara Barton’s Poem “The Women Who Went to the Field” (1892), 192

Clipper Ship, 194

Primary Document: Excerpts from the Journal of Alexander Van Valen Describing His Journey to California via Clipper Ship (1849), 196

Clothespin, 196

Coal-Mining Technologies, 197

Coil Magnet/Electromagnet, 199

Colgate, William (1783–1857), 200

Colored Female Free Produce Society, 201

Colt, Samuel (1814–1862), 202

Colt Revolver, 203

Columbiad Cannon, 204

Combine Harvester, 205

Compact Iron Stove, 207

Conestoga Wagon, 208

Primary Document: Excerpt from John G. Abbott’s Recollections of Traveling to California by Wagon Train (1852), 210

Corn Sheller, 211

Corset, 211

Coston, Martha (1826–1904), 213

Cowboy Hat (Stetson), 213

Crumpler, Rebecca (1831–1895), 214

Cylinder Pin Tumbler Lock, 216

Dahlgren Gun, 216

Deere, John (1804–1886) and Deere and Company, 217

Dental Chair, 219

Detachable Collar, 219

Dix, Dorothea (1802–1887), 220

Dustpan, 221

Eggbeater, 222

Electric Doorbell, 223

Electric Stove, 223

Electric Street Railway, 223

Elevator Safety Brake, 224

Equatorial Sextant, 225

Field, Cyrus West (1819–1892), 226

Fire Alarm Call Box, 227

Floating Dry Dock (1849), 228

Primary Document: Excerpt from Abraham Lincoln’s Patent Application for the Floating Dry Dock (1849), 229

Gas Well, 230

Gold-Mining Technologies, 231

Goodyear, Charles (1800–1860), 232

- Grain Elevator, 233
- Gridiron for Cooking, 234
- Hand-Cranked Ice Cream Maker, 234
- Health Reform, 235
- Henry, Joseph (1797–1878), 237
- Hoop Skirt, 238
- Horse-Drawn Streetcar, 239
 - Primary Document: Image of a Horse-Drawn Streetcar (c. 1920), 240
- Hospital Transport Service, Women’s Department, 240
- Howe, Elias (1819–1867), 241
- Howe Truss, 242
- Interchangeable Gun Parts, 243
- Inverted Microscope, 244
- Jervis, John B. (1795–1885), 245
- Land Mines, 245
- Long, Crawford Williamson (1815–1878), 246
- Machine/Gatling Gun, 247
- Mason Jar, 249
- Maynard, Edward (1813–1891), 249
- Maynard Carbine, 250
- McCormick, Cyrus (1809–1884), 252
 - Primary Document: Letter of Robert E. Lee to Cyrus McCormick Regarding the Curriculum at Washington College (1865), 253
- Mechanical Reaper, 254
- Merrick, Solymon (1806–1852), 255
- Military Technology (Civil War), 255
- Mitchell, Maria (1818–1889), 258
- Morse, Samuel F. B. (1791–1872), 260
- Morse Code, 261
- National Academy of Sciences (NAS), 262
- Nightingale Plan, 263
- North, Simeon (1765–1852), 264
- Omnibus System, 265
- Papermaking Machine, 266
- Pencil Eraser, 267
- Pepper (and Salt) Shaker, 267
- Perkins, Jacob (1766–1849), 267
- Platform Scale, 268
- Polished Steel Plow, 269
- Printing, 269
- Printing Telegraph, 271
- Pullman, George Mortimer (1831–1897), 273
- Railroad T-Rail and Tie, 273
- Railroads, 274
 - Primary Document: Pacific Railway Act (1862), 276
- Ratchet Wrench, 279
- Relay, 280
- Repeating Rifle, 280
- Roller Skates, 282
- Rotary Hook (for Sewing Machines), 283
- Rucker Ambulance, 283
- Safety Pin, 284
- Sewing Machine, Automated, 284
- Sewing Pattern, 286
- Solar Compass, 287
- Spar Torpedo, 288
- Steam Locomotive, 288
- Steam Shovel, 291
- Stevens, Robert Livingston (1787–1856), 292
- Strauss, Levi (1829–1902), 294
- Telegraph, 294
 - Primary Document: Act Authorizing Construction of a Transcontinental Telegraph (1855), 297
- Ten-Hour Movement, 297
 - Primary Document: Excerpt from the Preamble and Constitution of the Lowell Female Labor Reform Association (1846), 298
- Toothpaste, 299

Torpedo, 301
 Transatlantic Cable, 302
 Transverse Shuttle, 303
 Twine Knotter, 304
 Twist Drill, 304
 United States Capitol Building, Construction of, 304
 U.S. Sanitary Commission (USSC), 306

Vulcanization, 307
 Walker, Mary (1832–1919), 308
 Western Union Telegraph Company, 310
 Zipper, 311

Bibliography: Colonial America to 1865, 313
Index, 317

VOLUME 2: RECONSTRUCTION THROUGH WORLD WAR II

Section 1: The Rise of Industrialism, Reconstruction, and the Gilded Age (1866–1900), 1

Overview, 1

Abbe, Cleveland (1838–1916), 7

AC Generator and Transformer, 9

Primary Document: American Institute of
 Electrical Engineers (AIEE) Member
 Biography for William Stanley (1934), 10

AC Induction Motor, 10

Primary Document: Nikola Tesla's Patent for an
 AC Induction Motor (1896), 11

Adding Machine with Keys, 14

Amalgamated Clothing Workers of America
 (ACWA), 14

American Telephone and Telegraph Company
 (AT&T), 16

Asphalt, 17

Aspirin, 18

Barbed Wire, 19

Primary Document: Excerpts from an Article on
 Joseph F. Glidden and the Barb-Wire
 Industry (1884), 21

Batteries, 23

Bee Smoker, 24

Primary Document: Excerpt on the Use of a Bee
 Smoker from Moses Quinby's *Mysteries of
 Bee-Keeping Explained* (1853), 24

Bell, Alexander Graham (1847–1922), 26

Primary Document: Letter of Alexander Graham
 Bell to His Parents Describing His Idea for
 the Telephone (1874), 27

Berliner, Emile (1851–1929), 29

Brooklyn Bridge, 30

Camera, 31

Can Opener, 33

Carnegie, Andrew (1836–1919), 34

Carnegie Steel Mill, 35

Primary Document: Correspondence of Andrew
 Carnegie and Henry Clay Frick Regarding
 the Homestead Strike (1892), 37

Carpet Sweeper, 38

Carver, George Washington (1861–1943), 38

Primary Document: George Washington Carver
 Addresses Congress (1921), 41

Cash Register, 42

Celluloid, 42

Coca-Cola, 43

Cotton Candy Machine, 45

Crayons, 45

Curling Iron, 47

Diner (Horse-Drawn), 47

Dishwashing Machine, 48

Dow Chemical Company, 49

- du Pont, Pierre (1870–1954), 50
- DuPont Company, 52
- Duprey, Ana Roqué de (1853–1933), 54
- Duryea, Charles (1861–1938) and Frank (1869–1967), 54
- Earmuffs, 55
- Eastman, George (1854–1932), 56
- Eastman Kodak Company, 56
- Edison, Thomas (1847–1931), 57
- Electric Iron, 59
- Electric Lightbulb, 60
- Electricity, War of the Currents, 61
- Electrification, Urban, 63
- Escalator, 65
- Ferris Wheel, 66
 - Primary Document: Telegrams between Luther Rice and George Ferris Following the Successful Test of the Ferris Wheel (1893), 68
- Folding Cabinet Bed, 68
 - Primary Document: Patent for Folding Cabinet Bed (1885), 69
- Food Preservation, 70
- Fountain Pen, 71
- Frasch Process, 72
- Gas Transmission, 73
- General Electric, 74
- Goodrich, B. F. (1841–1888), 75
- Goodyear, Charles, Jr. (1833–1896), 76
- Hallidie, Andrew Smith (1836–1900), 76
- Harvard Computers, 77
 - Primary Document: Undated Photo of the Harvard Computers, 79
- Haynes, Elwood (1857–1925), 79
- Heyl, Henry (1842–1919), 80
- Ice Cream Soda, 81
- Inman, George (1895–1972), 82
- Iron Ship with Revolving Turret, 83
- Ironing Board, 83
- Jeans, 84
- Jockstrap, 86
- Jones, Amanda T. (1835–1914), 86
 - Primary Document: “The Soldier’s Mother” by Amanda T. Jones (1867), 87
- Kellogg, William Keith (1860–1951), 88
- Kelly, William (1811–1888), 89
- Kier, Samuel (1813–1874), 90
- Kinematoscope, 91
- Knight, Margaret (1838–1914), 91
- Lady Stitchers’ Union, 92
- Lawn Mower, Reel-Type, 93
- Lennox, David (1855–1947), 93
- Linotype Machine, 94
- Margarine, 95
- Matchbook Matches, 96
- Matzeliger, Jan Ernst (1852–1889), 96
- Maxim, Hudson (1853–1927), 97
- Metal Detector, 97
- Metal Electrode Weld, 98
- Metal Windmill, 99
- Military Technology (Post–Civil War through World War I), 100
- Motion Picture Camera, 102
- National Consumers League, 104
- National Institutes of Health (NIH), 105
- Niagara Falls Power Plant, 106
 - Primary Document: Excerpt from Nikola Tesla’s Commemoration Address for the Niagara Falls Power Plant (1897), 108

Office Technology (Pre–World War II), 112

Paper Bag, 114

Paper Clip, 114

Phonograph, 115

Primary Document: Roll Call of Companies at
the Phonograph Convention in Chicago
(1890), 119

Photographic Film, 120

Pipe Wrench, 121

Player Piano, 121

Portland Cement Mortar, 122

Punch Card Tabulator, 123

Quadruplex Telegraph, 124

Railroad Refrigerator Car, 125

Railroad Sleeping Car and Pullman Car, 126

Railroad Switch Systems, 127

Richards, Ellen Swallow (1842–1911), 128

Roebing, Emily (1843–1903), 129

Primary Document: Photograph of the Promenade
on the Brooklyn Bridge (1899), 131

Roebing, John (1806–1869), 131

Roll Film, 133

Roller Coaster, 133

Rotary Washing Machine, 134

Rowing Machine, 135

Saccharine, 135

Silo, 137

Skyscraper, 138

Soda Fountain, 140

Spork, 141

Steel Arched Bridge, 142

Stethoscope, Binaural, 143

Stockyards, 144

Primary Document: Photograph of Chicago’s
Union Stock Yards (1907), 145

Tape Measure, 146

Taylor, Frederick (1856–1915), 146

Tesla, Nikola (1856–1943), 147

Ticker Tape, 149

Tom Thumb Locomotive, 150

Primary Document: John Latrobe’s Description
of the *Tom Thumb* Locomotive (1830), 150

Track-Type Tractor, 152

Transcontinental Railroad, 153

Twine Self-Binding Harvester, 155

Typewriter and QWERTY, 155

Velocipede, 156

Vending Machine, 157

Vibrator, 158

Water Heater, 159

Westinghouse Air Brake, 160

World’s Fairs, 161

Wright, Wilbur (1867–1912) and Orville
(1871–1948), 164

Primary Document: Entry from Orville Wright’s
Diary of December 17, 1903, 166

Yerkes Observatory, 166

Section 2: The Progressive Era and the Roaring Twenties (1900–1929), 169

Overview, 169

Aerosol Spray Can, 176

Airplane, 176

Anderson, Mary (1866–1953), 179

Assembly Line, 179

Primary Document: Excerpt from Henry Ford’s
“The First Assembly Line” (1913), 181

Automobile Technologies (Pre–World War II), 181

Bakelite, 183

Band-Aid, 185

Bell Telephone Laboratories, 185

- Binney & Smith Inc., 186
- Birdseye, Clarence (1886–1956), 187
- Blender, 188
- Blodgett, Katherine (1898–1979), 188
- Boeing, William E. (1881–1956), 189
- Bottle-Making Machine, 190
- Bread Slicer and Wrapping Machine, 191
- Bryant, Alice (1862–1942), 192
- Cannon, Annie Jump (1863–1941), 192
- Carothers, Wallace (1896–1937), 194
- Christmas Tree Lights, 194
- Chuck Wagon, 195
- de Forest, Lee (1873–1961), 196
- Dickelman, Elizabeth (dates unknown), 197
- Dickerson, Mary Cynthia (1866–1923), 197
- Drew, Charles (1904–1950), 198
- Ductile Tungsten, 199
- Einstein, Albert (1879–1955), 199
- Empire State Building, 201
- Ford, Henry (1863–1947), 202
- Freon, 204
- Galvin, Paul Vincent (1895–1959), 205
- General Motors (GM), 206
- Gilbreth, Lillian (1878–1972), 208
- Gramophone/Victrola, 208
- Gumball Machine, 210
- Hewitt, Peter C. (1861–1921), 210
- Hoosier Cabinet, 212
- Hydroelectric Power, 212
- Jacob, Mary Phelps (1891–1970), 214
- Kettering, Charles F. (1876–1958), 215
- Lie Detector, 216
- Life Savers Candy, 217
- Marsh, Albert L. (1877–1944), 217
- McKnight, William L. (1887–1978), 218
- Midgley, Thomas (1889–1944), 219
- Morgan, Garrett (1877–1963), 220
- Motorcycle (Pre–World War II), 221
- National Advisory Committee for Aeronautics (NACA), 223
- Noether, Amalie Emmy (1882–1935), 224
- Olds, Ransom Eli (1864–1950), 225
- Panama Canal, 225
 - Primary Document: Excerpt from President Theodore Roosevelt’s Message to Congress After Returning from the Canal Zone in Panama (1906), 228
- Pennington, Mary Engle (1872–1952), 232
- Petroleum Industry (Pre–World War II), 233
- Pop-Up Toaster, 234
- Pushpin, 235
- Radio, 236
 - Primary Document: “Radio’s Real Uses” by E. E. Free, Science Editor for *The Forum* (1926), 239
- Rocky Mountain Laboratories, 240
- Safety Razor, 240
- Scotch Tape, 241
- Subway System of New York City, 242
- Talking Movies, 243
- Traffic Light, Electric, 245
- Triode Tube, 246
- Turbine Engine, Gas Powered, 247
- Washing Machine, Electric, 247
- Welding, Alternating Current, 248
- Welding, Automatic, 249

Section 3: The Great Depression and World War II (1930–1945), 251

Overview, 251

Alaska Highway, 257

Primary Document: Excerpt from Ruth Gruber’s Study of Highway Routes to Alaska (1941), 259

Atomic Bombs/Nuclear Weapons, 260

Avenger Field, 261

Primary Document: Letters of Mary Anna Martin Wyall, a Pilot Trainee at Avenger Airfield (1944), 262

B-17 Flying Fortress, 263

Big Science, 264

Blood Transfusion, 265

Bradberry, Henrietta (1903–1979), 266

Calutron Girls, 267

Clarke, Edith (1883–1959), 268

Curtiss-Wright Aeronautical Engineering Cadettes, 269

D Rations, 270

Electric Guitar, 270

Fermi, Enrico (1901–1954), 271

FM Radio, 272

Freeze-Dried Food, 273

Garbage Disposal, 273

Gas Mask, 274

Golden Gate Bridge, 274

Primary Document: Letter of Charles Ellis to the *San Francisco Chronicle* Regarding the Golden Gate Bridge (1930), 275

Helicopter, 276

Hoover Dam, 277

Primary Document: President Franklin D. Roosevelt’s Speech at the Dedication of Hoover Dam (1935), 280

Hydrogen Bomb, 283

Hydroponics, 284

International Ladies’ Garment Workers’ Union (ILGWU), 285

Primary Document: “The Uprising of the 20,000,” 286

Interstate Highway System, 287

Primary Document: Excerpt from the Federal-Aid Highway Act (1956), 289

Lamarr, Hedy (1914–2000), 290

Primary Document: Patent for Hedy Lamarr’s Frequency-Hopping System (1942), 292

Lange, Dorothea (1895–1965), 292

Lend-Lease Program (1941–1945), 293

Liberty Ships, 294

M&M’s, 295

M4 Sherman Tank, 295

Manhattan Project, 296

Mead, Margaret (1901–1978), 297

Microwave Oven, 299

Military Technology (World War II), 299

MIT Radiation Laboratory, 301

Neoprene, 302

Oppenheimer, J. Robert (1904–1967), 303

Paul, Les (1915–2009), 304

Penicillin, 306

pH Meter, 307

Photocopier, 307

Pinball and Arcade Games, 308

Plastic Wrap, 309

Radar, 309

Refrigerator, 310

Richter Scale, 311

Rocketry (Pre–Space Age), 311

Rosie the Riveter, 313

Primary Document: Excerpt from Interview with Maria Isabel Solis (2003), 315
 Schwinger, Julian (1918–1994), 316
 Semple, Ellen Churchill (1863–1932), 317
 SONAR, 318
 Submarine Technology, 319
 Tampon, 320
 Tea Bag, 321
 Telephone, 322

Television, 325
 Tennessee Valley Authority Electricity Project (TVA), 328
 Thomas, Vivien Theodore (1910–1985), 329
 Tizard Mission, 331
 Women's Airforce Service Pilots (WASPs), 331
 Wu, Chien-Shiung (1912–1997), 333

Bibliography: Reconstruction through World War II, 335
Index, 339

VOLUME 3: THE COLD WAR TO THE PRESENT

Section 1: The Cold War (1946–1979), 1

Overview, 1
 911 Emergency System, 8
 Agent Orange, 9
 “Air” Athletic Shoes, 11
 Antiballistic Missiles (ABMs), 11
 Antibiotic, 13
 Apollo Project, 14
 ARPANET, 16
 Aspartame, 18
 Association for Women in Mathematics (AWM), 19
 Atari, 20
 Automotive Technologies (Post–World War II), 22
 Baer, Ralph (1922–2014), 24
 Primary Document: Excerpt from Ralph Baer's Four-Page Paper Describing His Plans for Simple Video Games (1966), 25
 Bar Code Scanner, 25
 Benerito, Ruth Rogan (1916–2013), 27
 Biodiesel, 27
 Primary Document: Statement of Anne Steckel, the Vice President of Federal Affairs of the National Biodiesel Board, to the Senate Committee on Environment and Public Works (2016), 29

Birth Control Pill, 31
 Bomb Disposal Robots/Units, 33
 Brill, Yvonne Madalaine Claeys (1924–2013), 34
 Primary Document: Yvonne Brill's Patent for New Jet Propulsion Technology (1974), 35
 Brown, Marie Van Brittan (1922–1999), 35
 Bulletproof Vest/Kevlar, 36
 Carson, Rachel (1907–1964), 36
 Chlorofluorocarbons (CFCs), 38

1. The Rise of Industrialism, Reconstruction, and the Gilded Age (1866–1900)

OVERVIEW

During the Gilded Age, the U.S. Patent Office granted a record number of patents, more than any previous time in American history. The era forever changed nearly every aspect of American life, with innovations influencing everything from the mundane to the extraordinary. The early part of this era, commonly referred to as the Industrial Revolution because machines increasingly began to replace the work of human hands, spanned the 1830s through the 1890s. The defining issues of the industrialization of the United States were the development of industries and the evolution of single-ownership businesses and partnerships into corporations, with an economic shift away from rural, agricultural lifestyles as a way to make a living and toward seeing big business and industry as the likeliest pathway to economic independence. Taking its cue from the United Kingdom, America experienced a boom in industry that also resulted in population growth as in no other era. The social, political, and economic landscape evolved, morphing into a process that in some ways continues to this day. Marked by an explosion of technological innovation most notable in communications and transportation, the era was fraught with complications, hardship, and wonder. Despite the tumult of a country adjusting to life during and after Civil War in the 1860s, rather than hindering its continued course of technological innovation and its advances, it encouraged the country not only to continue but also to thrive throughout the war and into Reconstruction and the Gilded Age aptly named by Mark Twain, an author whose work harkened back to nostalgia for rural life.

Among the dynamics of post-Reconstruction America, industrial production began to be controlled by a relative few. One of those industrialists was Scottish immigrant, pacifist, and philanthropist Andrew Carnegie. His Carnegie Steel Mill realized a fortune in steel production while battling labor disputes during the 1890s with paid mercenaries, which led to loss of life. Ultimately, Carnegie's voice would be among other early voices challenging the Gilded Age ideas of displaying wealth and conspicuous consumption. Believing in the value of education, he would give away much of his wealth, demonstrated in the tremendous number of libraries and universities that he helped found with his fortune.

The most important manufacturing centers of America by the 1880s were located on the East Coast. Newark and Paterson, New Jersey, housed prominent textile factories in the world of silk, ribbons, cloth, and thread. Machines utilized the power of steam in engines and turbines on land while American ingenuity developed an efficient system of transport at sea with the sleek design of the clipper ships. With increased demand for goods and services, the demand for steel, iron, and oil catapulted manufacturing on American soil into action. One of the key innovations of the era was the Bessemer converter fueling the steel industry by converting iron into steel. Carnegie's would be the first steel company to utilize the converter. During the 1850s, petroleum discoveries in the hills of Pennsylvania and New York revealed that once oil was refined, it could be used for illuminating lamps on steamships and railroads. Also, by the 1880s, the building industry began erecting skyscrapers.

In general, development of cities was propelled by the wealthy, and transportation was an important

component. Powerful financiers and industrialists of the era provided capital, including J. Pierpont Morgan (1837–1913) and John Jacob Astor IV (1864–1912), himself an inventor and considered the wealthiest man of the era. John D. Rockefeller exemplified the era known as the Gilded Age with his profound wealth. He bought his way through competing oil companies, and he manipulated employees, competitors, business partners, and the public to create and maintain his oil monopoly, Standard Oil. Some historians define Rockefeller as an astute (and sometimes lucky) businessman who created an important American enterprise. Still others reasoned that Rockefeller's collusions with the railroads proved important business decisions, though they exemplified Rockefeller's greed.

The years following the end of Reconstruction heralded the Gilded Age (1878–1899); its name was taken from the title of a Mark Twain novel describing the culture of political corruption and materialistic excess he saw in 1870s America. As the business landscape in the United States continued to change, the landscapes of its cities shifted as well. Skyscrapers dotted the skyline of Chicago by 1884, utilizing steel in their construction to offset the losses resulting from the Chicago Fire of 1871. The completion of the world's first steel suspension bridge, the Brooklyn Bridge, in 1883, connected New York City's Manhattan Island to Brooklyn, furthering America's rise as an industrial force.

The social impact crossed a broad spectrum of social repercussions as well as benefits. Among them were increased goods, services, and jobs. This generated taxes going into city, state, and federal coffers. Larger consequences appeared in damages to the environment and exploitation of its men, women, and child workers, widening the gaps between classes. For workers, long hours, low chances for advancement, small wages, and lack of safety protocols on the job created untold hardship. With the rise of industry came examinations by newspaper organizations responding to managers' exploitation of employees. Muckrakers exposed, through journalistic investigation, the inequities of exploitation by corrupt corporate and political entities. Government regulation and unionization efforts contributed to controlling the negative impact of industrialization.

Reconstructing after the Civil War

The Civil War furthered the already rapid rise of industry, notably in the steel industry, but the amplified demand for supplies—namely munitions and food along with transport for troops—also contributed to an increased demand for railroads. Commercially canned food proved safe and easier to transport, supplying the Union Army more efficiently than the Confederate Army as the northern United States had already had a burgeoning factory system in place before the war. Set against a backdrop of a divided country and its subsequent attempts at reunification, the periods following the American Civil War (1861–1865), referred to as Reconstruction (1866–1877), were socially fraught with conflict and adjustment. Scholars wrestled with the impact of Reconstruction for generations. With the defeat of the agrarian South (which had traditionally blocked laws aimed at promoting industrialization), the North turned its sight toward Reconstruction. A cheap supply of immigrant labor willing to work in factories in the North for bare subsistence wages provided an easily accessible and abundant supply of natural resources, especially coal and iron ore, to consumers. Later on, government support for industry with protective tariffs, loans, and subsidies for internal improvements and transportation projects all contributed to the corporate culture, the massive profits being acquired largely by capitalists. U.S. industrialists freely adapted and adopted technology from England. At this time, inventors and innovators relied upon investors and the patronage of the wealthy few to support the work of research and development.

Mills, breweries, and factories relied upon steam-powered engines by the 1880s. With the introduction of steam engines, the transport time for goods and services increased a hundredfold. This redefined what it meant to be wealthy for a limited few Americans. Rather than measure financial worth in terms of acreage, wealth was now defined in terms of dollars and how corporate entities efficiently utilized a labor force. Before the Industrial Revolution, power beyond the corporal was limited to wind and water. New sources of power in coal and gas reduced the amount of labor need to effectively complete jobs. Horsepower for generations had supplied the transport needs of a

growing population. A new use for the steam engine's mechanical power included the first oil well dug in Titusville, Pennsylvania, in 1859.

Bridging the Continent

The Transcontinental Railroad was the first American railway system connecting the eastern and western halves of the United States. Considered the most extraordinary enterprise ever undertaken in the 19th century, President Lincoln endorsed the Transcontinental Railroad finally authorized by Congress in 1862. The Pacific Railroad Act charged investors from Sacramento, California, to form the Central Pacific Railroad Company and establish tracks eastward, and the Union Pacific Railroad Company laid railroad tracks heading westward. Both were tasked to complete the enormous undertaking in the spirit of a competitive race, with the winner receiving a monetary bonus—though this bonus was not shared with the largely Chinese and Irish immigrants who provided most of the actual labor. Also, East pitted against West in competition resulted in hastily laid track that had to be relaid later as mounting accidents revealed the faulty workmanship. Completed in 1869, the project greatly influenced the transport of people, goods, and services and had the potential to reunite a divided country recovering from the Civil War.

Also in 1869, a telegraph sent from Promontory Point, Utah, across America announced the completion of the Transcontinental Railroad. The impact of the final golden spike driven into the last railroad tie reverberated throughout the country. The implementation of refrigerator cars by J. B. Sutherland allowed for transport of food at greater distances. Cattle shipments from the open ranges of the American West to the East Coast began in 1870. A number of railway systems had appeared throughout the United States, but none came close to connecting the East and West Coasts like the Transcontinental did. This affected not only food and cattle transport but also travel. Technological advances that followed included the railroad signal, air brake, and switch system by George Westinghouse, along with the sleeping car, which added comfort on passenger trains, furthering the success of the railroad system.

Not without consequences, the rapid expansion of the Transcontinental across thousands of acres of land took a heavy toll upon not only Native American populations but immigrants as well. While Native Americans continued to struggle with losses from broken treaties and continued encroachment by European expansion into Native territories, Chinese immigrants to California during the Gold Rush had discovered a place for their industry in building the historic Transcontinental Railroad, often under harsh conditions. But they faced legal discrimination and racism once the project was completed.

As technological advances increased in the eastern United States, industry in the American South increased post-Reconstruction. Although not on the same scale as in the North, and still recovering from the effects of life under wartime conditions, railroads, iron, and steel industries along with textile manufacturing had begun in the Southern regions due to low taxes and a labor force of largely female heads of households willing to accept subsistence wages. Often, these families uprooted themselves and moved to mill towns where employment advantages outweighed the post-Civil War devastation to family farms. Although this created jobs for households that were often without men, it kept these households dependent within the confines of the mill town system of high credit rates, long working hours and debt to factory owners, who very often were funded with Northern money.

The Southern factory system offered white households some semblance of a living, but for post-Civil War freedwomen and men, it remained a closed door except for the unskilled in labor. Freedmen and women who returned to plantations for their livelihoods post-Emancipation found themselves in a system of farm labor known as “sharecropping.” A contract was drawn up in partnership with a white landowner, and the labor provided by blacks in reality financially benefited the landowner, as any profits went back to him as he acted as both landlord and lender.

Along with the telegraph, the locomotive train allowed more Americans to stay connected while allowing for travel farther and quicker across the land than before. The American West witnessed other innovations with far-reaching consequences. The rise of

stockyards, twine self-binding harvesters, and track-type tractors provided efficiency and expediency on ranches and farms. In 1868, a patent was issued to Michael Kelly for barbed wire, metal fencing designed with short, twisted wire spikes to contain livestock and mark boundaries against trespassers. Mostly utilized to keep roaming livestock contained on a ranch, the impact on local Native populations was heavy, as it cut off water and hunting and diminished access to food sources. This also contributed to the end of the cowboy's long-haul cattle drives of previous generations as open land narrowed to private ranches enclosed by barbed-wire fencing, effectively cutting off access to well-established cattle drive routes long honored as shared open space. Barbed wire was not the only innovation to affect the wide-open expanses of the American West.

The Rise of Female Entrepreneurship

Women were not new to patenting mechanics or labor-saving devices for household or farm. Women's innovations as well as improvements on the designs of already-established devices ran the gamut of personal health and hygiene to ranch and household equipment and food production. Women's achievements and innovations often were accomplished anonymously, as social conventions of the day did not allow women to step out of their roles as homemakers, mothers, and helpmates to men. Nevertheless, records of the U.S. Patent Office reflect that many women defied gender conventions, repeatedly applying for patents under their own names. Many also patented their efforts under assumed male names masking their gender. Likewise, many women may have shared their work with husbands or another close male in order to achieve their goals.

One forum that allowed female participation was at World's Fairs and expositions in designated "women's sections," where acknowledgment of their inventions conformed to the accepted spheres. Patents by women appear in the 1800s for improving farm equipment such as a comb cotton-ginning device. Gelatin as a dessert was born in the kitchen of Rose Markward Knox (1857–1959), the inventor of flavored gelatin. Ice cream makers, eggbeaters, and dough mixers,

along with improvements on machines for sewing, ironing boards, and washing clothes and dishes, as well as for clothes-washing powder and liquid, appeared during the 1880s and 1890s. Many improved upon already-existing inventions. The automatic dishwasher idea came to Josephine Cochran in 1886. Margaret Colvin demonstrated her rotary washing machine at the Columbian Exposition in 1893. Colvin's patent for a washing machine was not the first; however, hers worked better than earlier versions. Sarah Goode's space-saving cabinet that unfolded to a bed became the first known patent by an African American woman in 1885.

Notable inventions of household improvements by men included the can opener designed in 1870 by William Lyman. Inventor Hiram Maxim not only invented the curling iron in 1866 but later the first successfully operated automatic machine gun in 1884. The shoe-lasting machine invented in 1883 by South American immigrant Jan E. Matzeliger revolutionized the footwear industry by speeding up the process of shoemaking.

Socially, the concept of leisure time and entertainment, still a new idea in mid-to-late-19th-century America, grew, thanks to the fact that industrialism brought in extra income and shorter workdays for the working classes compared to life on farms. Without duties associated with farm life, transplants to major cities found themselves with spare time. Amusement parks with roller coasters fueled recreation for a public looking for ways to spend its extra income and free time. What translated to leisure time for some, however, meant overwork, unsafe working conditions, exploitation, illness, and even loss of life. The rise in industrialism came with the demands for an increased labor force, and it included children. Children as young as seven, eight, and nine years of age were employed as operators in textile mills and coal mines, or they were sent to street corners to sell newspapers and produce. It would not be until the 1930s that the government enacted federal legislation banning underage children from the workforce. Reform often came in the mode of union membership. The Lady Stitcher's Union was one such union, organizing 3,000 women in 1886 who protested intolerable working conditions. Later, the International Garment Workers of America

would provide an even stronger platform for female immigrant sweatshop laborers in the wake of the Triangle Shirtwaist Factory Fire of 1911.

The Industrial Revolution Comes of Age

Technological advancement in 19th-century America crossed a broad spectrum of disciplines with the foremost breakthroughs in electrical energy, communication, and transportation. Financiers, industrialists, and entrepreneurs all shared an interest in unheard-of financial gain, all the while transforming the way Americans traveled, lived, and worked. Time and speed took on completely new dimensions as communication and transportation accelerated American life at rates unimaginable a generation earlier. The telegraph transmitted signals and sped communication faster than previously thought possible between cities. A transatlantic telegraph cable to Europe implemented by Cyrus W. Field in 1866 forever transformed communication between continents, which would prove important in the waging of world wars in later eras. Guglielmo Marconi's innovation sent radio signals across the ocean with similar impact. By 1876, the U.S. Patent Office registered a device that could transport human voices, allowing for communication across great distances. Inventors like Alexander Graham Bell (1847–1922) founded the Bell Telephone Company in 1877, and by 1899, it had become the American Telegraph and Telephone Company. Thomas Edison's (1847–1932) experiments and inventions of electricity and the electric lightbulb propelled the Edison Electric Light Company, chartered in 1878.

The information age spun forward rapidly as Americans utilized electric current not only in business but also socially. Americans of all walks of life took advantage of electric train cars, strolled through towns lit by electric lights, and forwent candles and gaslights in favor of electric lights at home in their parlors and at work in their offices.

Like many innovations of the era, America's first subway was funded by private industrialists. Early transportation had been horse-drawn railroads or streetcars. The first electrified streetcar system in Boston led to realizing the dream of a public subway system by inventor and engineer Frank Julian Sprague.

Sprague saw the first subway while in London in 1863—a coal-powered steam engine train that ran under the city. Created through the labor of Italian and Irish immigrants, America's first subway finished in 1897, built of concrete and steel.

The Industrialization of Leisure

The innovations of the 19th century not only harnessed energy far more efficiently, but they introduced time as a commodity and confronted class distinctions. Saving time meant more efficiency, and efficiency translated to dollars. The invention of elevators sped the transport of humans quickly to their destinations. Adding machines and typewriters cut the time it took to compose a letter more efficiently; then paper clips kept it all together. An expanding concept of freedom based upon individual fulfillment and personal self-determination evolved into participation in the expanding consumer marketplace and the freedom of leisure time.

Time as a commodity translated to a new concept of leisure transcending social class. Transitioning from a rural, farm, agrarian economy to the industrial, business-based economy found in cities, America found itself with leisure time. With dedicated hours in offices or service industries or factories, this labor force of women and men, after sending paychecks back home, found themselves with not only a little extra money but extra time to pursue life outside an office or factory. The impact was immeasurable, as it not only created industries and activities dedicated to fun, but it proved a great equalizer of the social classes. For the first time, factory workers dressed in their best Sunday clothes could spend the afternoon rubbing elbows with the elites as well as other factory workers enjoying amusements not heard of a decade earlier, redefining social mores and behavior. Luna Park and later Coney Island are case studies in culture rebelling against the stifling constraints of the Victorian Era. They challenged the ideals along with the social order of the time with regard to how people conducted themselves in public with each other.

New York's Central Park and Chicago's Columbian Exposition of 1893 are prime examples of the decorum expected in late-Victorian-era America.

There were expectations for how these amusements should be experienced. In keeping with Victorian ideals, Central Park and events like the Columbian Exposition were expected to maintain social order as well as create recreations for the public. The public was expected to conduct itself in a quiet, reserved manner while engaged in activities that were designed to promote learning and cultural refinement.

Frederick Law Olmsted, in collaboration with Calvert Vaux, designed New York's Central Park in 1858. It was intended as a retreat from the tumult of the city for all classes to enjoy. Olmsted's intentions, however, were to further the Victorian era's code of conduct to include a moral element intent on impressing upon the lower classes the necessity of conformity while endorsing upper-class lifestyles. Genteel behavior was the order of the day, and refinement was the rule. Traditional amusements of the Victorian era were carried out in venues such as bathing facilities band pavilions, dance halls, vaudeville theaters, and circus attractions. One might also find sporting events such as softball, football, and boxing. Any type of mechanical amusement with elaborate settings would be certain to draw a crowd. Still, most were considered spectator activities.

Early on, Coney Island was initially a dichotomy; one side of the park was for elites and the other half for gamblers and prostitutes. As time passed, the park opened for both, merging shop attendants and upper classes, where genteel behavior and refinement was not the rule. It was far from the skyscrapers of the city, offering new technology and architecture that had never been seen before. It also offered direct interaction with the amusements rather than passive watching from the sidelines, with no hint of educational value. The biggest impact that Coney Island had, however, was that it broke down restrictive social barriers imposed by Victorian standards and allowed for more freedom of exchange between the classes and between the sexes. This is what made it so different from other major amusements of 19th and early 20th century.

In 1861, Thomas Edison applied for a patent for a Kinematoscope, an early form of the motion picture camera. This device would display photos as if they were moving when someone simply wound the crank,

allowing the multiple photos to fall into place to give the illusion of movement. Edison's presentation at the World's Columbian Exposition of 1883 of his Kinetograph foreshadowed the birth of the "picture shows," or movies, using the celluloid film invented in 1889 by George Eastman of the Eastman Kodak Company.

Public Health and the Modern City

Across these decades, major strides would be made in medical sciences with government involvement, establishing overseeing bodies for public health and environment. The National Institutes of Health, formed in the 1870s, established a laboratory for the study of bacteria. By the end of the 19th century, the connection made between germs, their transmission, and hygiene and cleanliness did much to reduce mortality rates from deadly infections of typhoid fever and cholera. Penicillin and other new drugs reduced mortality rates among women and men. Women were living longer, and the birthrate continued to fall. Infant fatality also was on the decline in the United States. Despite progress in the field of public health, tuberculosis was still a health hazard. The spittoon or cuspidor, utilized by Americans to comply with laws limiting spitting in public, was still a fixture in public places into the 20th century, even though science had long known that any spitting could transmit tuberculosis.

Progress in public health and environmental issues came slowly. With the rise of factories and increased mining, not only did land and air quality suffer, but human health and significant loss of life came from heavy metal poisoning. Examples include the lung diseases of coal miners, as well as the wood and cigarette smoke that affected the broader population. The mines proved an environmental nightmare well into the 21st century. Diseases such as cholera and typhoid fever, whose route of transmission was unfiltered water, remained constant until the discovery of chlorine additives to public water sources in New Jersey dramatically reduced incidences of typhoid fever. Meanwhile, the harnessing of solar power to drive mechanical pursuits as an economical way to fuel devices like steam engines and the printing press went by the wayside as the use of coal and then petroleum

increased, with drastic environmental impact. The environmental cost to American soil due to industrialization would take a toll on riverways, while air quality in steel towns remains profoundly problematic to this day.

Late 19th and early 20th-century American technology and innovation centered on the production of goods and the early development of consumerism. Greater communication capabilities sparked the rise of newspaper muckrakers, who addressed profound social, political, and economic issues brought by the rise of industrialism and corporations. These had fueled tremendous wealth for a relative few, creating a widening gap between the wealthy and the working class and creating monopolies in industry.

By 1901, Theodore Roosevelt (1858–1919) would be the 26th president of the United States. He is considered the first modern president because of his support for progressivism, but principally because he embraced government responsibility for the common welfare of the nation both domestically and in foreign policy. Domestically, this meant using the office of the president to try to balance the power of big business (trust busting) and to reform politics to better address the tribulations caused by the Industrial Revolution of the earlier era. The Progressive Movement furthered reforms begun by the Populist Movement, tackling issues such as Prohibition, child labor laws, minimum wage, tenement house reform, antimonopoly legislation, food and drug regulation, and trust busting.

Brothers Wilbur and Orville Wright's successes with airplane flight catapulted Americans into the sky, leading the country into the next century, when Americans would travel into space.

Abbe, Cleveland (1838–1916)

Weather forecasting dates to the middle of the 19th century and can be largely attributed to the efforts of one man: Cleveland Abbe. It was his work and vision at the precursor of the National Weather Service that resulted in a widespread network capable of issuing reliable weather forecasts and severe weather warnings. Abbe also advocated for time zones in the United States.

Cleveland Abbe was born in 1838 in New York City. He was an astronomer and meteorologist who went by the nickname “Old Probability” due to his weather forecasting work. Abbe began this work during his time as the director of the Cincinnati Observatory in Cincinnati, Ohio, where he generated daily weather maps, weather forecasts, and even telegraphic weather reports. There, he also developed a code to transmit weather data, which minimized word count and allowed for faster and more efficient decoding of weather messages.

In 1872, he moved from the Cincinnati Observatory to the U.S. Weather Bureau and became the Bureau's chief meteorologist. Abbe's particular strength came in being able to generate weather forecasts and not simply summaries of already-past weather events. As the U.S. Weather Bureau was still very much in its infancy, for a short time, Abbe shouldered the workload while he trained others in weather forecasting based on scientific principles. He enlisted

The father of modern weather forecasting, Cleveland Abbe became chief meteorologist at the U.S. Weather Bureau in 1871. (Library of Congress)

young college graduates, who at the time were men only, to work at the Bureau.

In 1872, Abbe also founded the *Monthly Weather Review*, a scholarly journal devoted to weather forecasting. The *Review* was first a government publication under the auspices of the U.S. Army Signal Corps (of which the U.S. Weather Bureau was a department). The Weather Bureau was transferred to the U.S. Department of Agriculture in 1891, after which that department published the *Review*. From 1970 to 1973, the National Oceanic and Atmospheric Administration took over the Weather Bureau and the *Review*, but in 1974, the *Review*'s publication shifted to the American Meteorological Society, which still publishes the well-respected journal.

In 1891, when Congress moved the institution under the Department of Agriculture, most of Abbe's weather disciples followed. It was through his

mentorship and instruction that Abbe was able to set standards and establish the tone for the weather forecasting so familiar today. He insisted that every forecast that was issued had to cover weather, temperature, wind direction, and barometric pressure in precise and clear language. Cleveland Abbe recognized that for data from multiple stations across the country to be useful, they all had to be consistent in their time-keeping. This gave birth to his advocacy for time zones. He divided the United States into four standard time zones and published a paper titled "Report on Standard Time" in 1879, which played a large role in the government's decision to adopt a time zone system.

As the U.S. Weather Bureau became more established, Abbe realized the need for not just trained personnel but also technological advances. Along with his colleagues, he worked on calibrating various instruments, and in time, they designed and built instruments that pushed weather forecasting technology forward. Abbe had the foresight to realize that accurate weather predictions require a lot of data, often from outside the boundaries of the United States. Therefore, he bought and calibrated instruments adapted to international standards that facilitated international cooperation in weather data sharing.

Cleveland Abbe's contributions to his field were widely recognized. He published almost 300 scientific papers, and his authority was well known. He was one of the founders of the National Geographic Society. Starting from 1886, he was a professor at Columbian College, now George Washington University, and he was a lecturer at Johns Hopkins University from 1896 to 1914. He was awarded a PhD in 1891 from the City College of New York, his alma mater. Additionally, he received honorary degrees from the University of Michigan in 1888 and the University of Glasgow in 1896. Among his many accolades, Cleveland Abbe was an associate fellow of the American Academy of Arts and Sciences and also a recipient of the Symons Gold Medal from the Royal Meteorological Society as well as the Public Welfare Medal and the Marcellus Hartley Medal from the National Academy of Sciences. He died in 1916 in Maryland.

AC Generator and Transformer

The invention of alternating current (AC) generators and transformers was instrumental to the development of a workable electrical power distribution system. The first working AC generator was created in 1832 by Parisian inventor Hippolyte Pixii (1808–1835) and was steadily improved throughout the 19th century by other inventors, including William Stanley Jr. (1858–1916) and Nikola Tesla (1856–1943).

The first commercially successful AC transformer was produced by William Stanley Jr. (1858–1916) in 1883. Stanley did not invent the transformer; his design was based on earlier designs, such as the one created in 1882 by Lucien Gaulard (1850–1888) and John Dixon Gibbs (1834–1912).

Stanley was born in New York City and studied law at Yale University before leaving college to work in the nascent electric industry. During the early 1880s, he developed his understanding of electromagnetism and experimented with converting direct current (DC) to AC. In 1884, he went to work for George Westinghouse (1846–1914) and in 1885 was promoted to chief engineer.

That same year, Gaulard and Gibbs demonstrated a "secondary generator" in Italy. This transformer stepped down the dangerous high-voltage AC from transmission lines to lower voltages, making it safer and useful for powering lights and other equipment. Westinghouse bought the rights to their design and, at Stanley's request, ordered a 500-volt Siemens alternator (a type of generator) and a Gaulard and Gibbs transformer.

Stanley realized that the transformer was inefficient and set about making improvements. He first created an *E*-shaped core and wrapped the wiring in a way that provided better insulation. His design used parallel linkages, which helped to maintain the stability of the transformer's loads. Stanley also developed his own generator design to replace the Siemens alternator.

On March 20, 1886, Stanley demonstrated a fully working high-voltage AC power system in Great Barrington, Massachusetts. Wires were draped in elm trees along Main Street, and the generator and steam engine were housed in a disused factory south of town. The "Great Barrington Electrification" relied on Stanley's transformers, which were capable of converting a 500-volt generator output into 3,000 volts and stepping the voltage back down to 500 volts.

The demonstration was another salvo in the ongoing "war of the currents." Great Barrington already had an Edison direct current (DC) power system installed, but Stanley's AC power system proved it was able to handle more customers with less loss of power. Despite some problems with the generator, its success convinced Westinghouse to pursue AC power systems instead of DC systems.

In 1890, Stanley left Westinghouse and formed the Stanley Electric Manufacturing Company, which made and sold transformers. However, in 1903, the company was acquired by Westinghouse after a court battle over patent rights.

Primary Document: American Institute of Electrical Engineers (AIEE) Member Biography for William Stanley (1934)

Although William Stanley died in 1916, the American Institute for Electrical Engineers (AIEE), a society to which Stanley belonged for many years, continued to recognize his contributions to electrical studies well after his death. The following is a biographical sketch honoring Stanley that appeared in the Institute's journal in 1934.

William Stanley was very prominent among electrical inventors and engineers who made possible long-distance light and power transmission; his inventions on the transformer and early work in the development of the a-c system contributed greatly to the advancement of the electrical art. During the earlier period of his career he was responsible for several incandescent lamp inventions, while in the employ of the United States Electric Company (1879–1881) and the Swan Electric company (1882–1883). From 1883 to 1884 he experimented on storage batteries and other apparatus in a private laboratory at Englewood, N.J. He then became associated with the Westinghouse organization, and installed and

equipped an incandescent lamp factory at Swissvale, Pa. In 1885, when because of illness he removed from Pittsburgh to Great Barrington, Mass., he set up a plant incorporating his ideas on long-distance light and power transmission, which distributed to the town 500 volts through transformers connected in multiple. The Westinghouse Company then took over the manufacturing details and installed the Stanley apparatus at Niagara Falls. In 1890 Mr. Stanley organized the Stanley Electric Manufacturing Company, which made the first of a long series of installations of the multiphase transmission system in 1894 at Housatonic, Mass., operating at 2,000 volts. In 1898 he organized the Stanley Instrument company. He also carried on an extensive consulting practice, until his death on May 14, 1916. He served the Institute on the Edison medal committee, from 1914 to 1916. He was born November 22, 1858, in Brooklyn, N.Y.

AC Induction Motor

The alternating current (AC) induction motor was patented by Croatian American inventor Nikola Tesla (1856–1943) in 1888. Tesla's motor became a mainstay of the electrical industry due to its reliability and ease of maintenance, and it remains in widespread use today.

The principle of electromagnetic induction was discovered in the 1820s by English scientist Michael Faraday (1791–1867) and American scientist Joseph Henry (1797–1878) when they found that a magnetic field moving across a wire would produce an electric current. Throughout the early 19th century, scientists and engineers worldwide worked to develop alternating current into a workable electrical power system. Direct current motors were the norm, and existing alternating current motors were unreliable.

Tesla was working in France when he had an idea for building a motor that would use the electric current produced (induced) by a rotating magnetic field to provide torque for the motor. He realized that such a motor could be designed that so that it used a nonmoving stator and a moving armature, and would not need mechanical contacts.

In 1885, Italian physicist Galileo Ferraris (1847–1897) constructed an induction motor that used two-phase alternating current. But Ferraris did not patent his work; instead, he published his findings, which were quickly picked up by other scientists and engineers, including Tesla.

In 1887, Tesla demonstrated a working model of his induction motor. In October and November that year, he filed for patents for his two-phase induction motor AC system. On May 1, 1888, he was awarded patent number 381,968 for his "Electro Magnetic Motor." Tesla

presented his research on the motor at the May 16, 1888, meeting of the American Institute of Electrical Engineers. Shortly thereafter, he received an offer of employment from Westinghouse to work as a consultant.

The new motor design proved to be workable and quite versatile. Within two years, Tesla patented a series of modifications to his induction motor design, including a variable-speed option and a motor that would run from a polyphase power supply. His motors were also capable of starting even when heavy loads were applied to them, which made them well suited for industrial applications.

Tesla would later become embroiled in court battles to prove his patent claim for the AC induction motor. During the first court case, held in 1901 in Catskill, New York, the judge ruled in Tesla's favor, but later the Circuit Court of Appeals overturned the verdict. However, in 1905, the courts again ruled in favor of Tesla.

Primary Document: Nikola Tesla's Patent for an AC Induction Motor (1896)

The following is the text of Nikola Tesla's patent for an alternating current motor, an invention that many people believe deserves to be listed in the top 10 inventions of all time.

UNITED STATES PATENT OFFICE.

NIKOLA TESLA, OF NEW YORK, N. Y., ASSIGNOR TO THE TESLA ELECTRIC COMPANY, OF SAME PLACE.

TESLA PATENT 555,190 ALTERNATING MOTOR.

SPECIFICATION forming part of Letters Patent No. 555,190, dated February 25, 1896.

Application filed May 15, 1888. Serial No. 273,993. (No model.)

To all whom it may concern:

Be it known that I, NIKOLA TESLA, a citizen of the United States, residing at New York, in the county and State of New York, have invented certain new

and useful Improvements in Electromagnetic Motors, of which the following is a specification, reference being had to the drawings accompanying and forming a part of the same.

In former patents granted to me—notably, Patents Nos. 381,968 and 382,280, of May 1, 1888—I have shown and described a system for the electrical transmission of power characterized by the following particulars: The motor contains independent energizing-circuits and the generator has corresponding induced or current-generating circuits which are connected by independent line-circuits with those of the motor, the said circuits being independent in the sense only that the distinctive relations of the currents produced, transmitted and utilized in each are preserved to produce their proper conjoint effect. The disposition of the generator coils or circuits is such that the currents developed therein and transmitted therefrom to the motor will have a certain difference of phase—for example, so that the maximum periods of the currents generated in one of such circuits coincide with the minimum periods of the currents produced in

the other circuit, and the corresponding energizing-circuits of the motor are so arranged that the two currents co-operate to effect a progressive shifting of the magnetic poles or the points of maximum magnetic effect in the motor, in consequence of which a rotation of its movable element is maintained.

My present invention pertains to this system of electrical transmission of power, its novel and distinguishing feature, however, being a special means for generating or producing in the two motor-circuits the alternating current necessary for the operation of the motor, for while in the instances referred to I produce both currents directly by a magneto-electric machine in the present instance I generate or produce in but one of the circuits of the motor directly an alternating current, and by means of such current induce in the other energizing-motor circuit the other alternating current necessary for its operation.

When the two currents are both produced in the magneto-electric machine, it will be observed that the two line or transmitting circuits will of necessity extend the entire distance from the generator to the motor; but by the plan herein provided one line-circuit only is required, as the circuit from the generator and the other are brought into inductive relation to each other in the motor itself.

The following is illustrative of a means by which I secure this result in accordance with my present invention: I employ as a motor, for example, a subdivided annular field-magnet within which is mounted a suitable armature, as a cylinder or disk, wound with two coils at right angles, each of which forms a closed circuit. On opposite sides of the annular field-magnet I wind two coils of insulated wire of a size adapted to carry the current from the generator. Over these coils, or close to them, in any of the well-understood ways, I wind secondary coils. I also wind on the annular field-magnet midway between the first-mentioned coils a pair of coils which I connect up in circuit with the secondary coils.

The last pair of coils I make of finer wire than the main or line and secondary coils, and with a greater number of convolutions, that they may have a greater relative magnetizing effect than either of the others.

By connecting up the main coils in circuit with a generator of alternating currents, the armature of the motor will be rotated. I have assumed that this action

is explained by the following theory: A current-impulse on the line passing through the main coils establishes the magnetic poles of the annular field-magnets at points midway between said coils; but this impulse produces in the secondary coils a current differing in phase from the first, which, circulating through the second pair of energizing-coils, tends to establish the pole at points ninety degrees removed from their first position, with the result of producing a movement or shifting of the poles in obedience to the combined magnetizing effect of the two sets of coils. This shifting, continued by each successive current-impulse, establishes what may be termed a "rotary effort," and operates to maintain the armature in rotation.

In the drawings annexed I have shown, in Figure 1, an alternating-current generator connected with a motor shown diagrammatically and constructed in accordance with my invention, and in Fig. 2 a diagram of a modified form of motor.

A designates any ordinary form of alternating-current generator, and B B the line-wires for connecting the same with the motor.

C is the annular field-magnet of the motor.

D D are two main coils wound on opposite sides of the ring or annular field and connected up with the line and having a tendency to magnify the ring C with opposite poles midway between the two coils.

E E are two other magnetizing-coils wound midway between the coils D D, but having a stronger magnetizing influence for a current of given strength than coils D D.

F F are the secondary coils, which are associated with the main coils D D. They are in circuits which include the coils E E, respectively, the connections being made in such order that currents induced in coils F and circulating in coils E will act in opposition to those in coils E in so far only as the location of the magnetic poles in the ring C is concerned.

The armature may be of any of the forms used by me in my alternating-current system, and is shown as wound with two closed coils G H at right angles to each other.

In order to prolong the magnetizing effect of the induced currents in producing a shifting of the poles, I have carried the principle of the construction

exhibited in Fig. 1 further, thereby obtaining a stronger and better rotary effect.

Referring to Fig 2, C is an annular field-magnet having three pairs or oppositely-located sets of polar projections K L M. Upon one pair of these projections, as K, the main energizing-coils D are wound. Over these are wound the secondary coils E. On the next polar projections L L are wound the second energizing-coils F, which are in circuit with coils E. Tertiary-induced coils E' are then wound over the coils F, and on the remaining polar projections M the third energizing-coils F' are wound and connected up in the circuit of the tertiary coils E'.

The cylindrical or disk armature core N in this motor has polar projections wound with coils O, forming closed circuits. My object in constructing the motor in this way is to effect more perfectly the shifting of the points of maximum magnetic effect. For, assuming the operation of the motor to be due to the action above set forth, the first effect of a current-impulse in this motor will be to magnetize the pole-pieces K K; but the current thereby induced in coils E magnetizes the pole-pieces L, and the current induced in turn in coils E' magnetizes the pole-pieces M. The pole-pieces are not magnetized, at least to their full extent, simultaneously by this means; but there is enough of a retardation or delay to produce a rotary effect or influence upon the armature. The application of this principle is not limited to the special forms of motor herein shown, as any of the double-circuit alternating-current motors invented by me and described in former Letters Patent to me may be adapted to the same purpose.

This invention, moreover, is not limited to the specific means herein shown for inducing in one energizing-circuit of the motor the currents necessary for co-operating with the primary current of the generator for producing the progressive shifting of the poles or points of maximum magnetic effect.

I believe that I am the first to produce any kind of motor adapted to be operated by alternating currents and characterized by any arrangement of independent circuits brought into inductive relation so as to produce a rotary effort or effect due to the conjoint action of alternating currents from a source of supply in one of the motor-circuits and alternating currents induced by the first-named currents in the other

circuit, and this without reference to the specific character or arrangement of the said two circuits in the motor.

What I therefore claim as my invention is—

1. In an electromagnetic motor, the combination of independent energizing-circuits, one adapted to be connected with a source of alternating current, the other arranged in inductive relation to the said first circuit whereby the motor will be operated by the resultant action of the two circuits, as set forth.
2. The combination in an electromagnetic motor, with an alternating coil or conductor and a closed-circuit conductor in inductive relation thereto, of an armature mounted so as to be within the field produced by the coil and closed conductor, as set forth.
3. The combination in an electromagnetic motor, with energizing-coils adapted to be connected with the generator of induced coils and independent energizing-coils in circuit therewith and arranged to produce a shifting movement of the points of maximum magnetic effect of the motor, as set forth.
4. The combination in an electromagnetic motor of a series of independent energizing-coils or sets of coils and induced coils wound on all the energizing-coils or sets of coils but the last of the series, the first energizing-coil or set of coils being included in circuit with a generator and each succeeding energizing-coil or set of coils being in circuit with the induced coils of the next preceding energizing-coils of the series.
5. In a system for electrical transmission of power the combination of an alternating-current generator, a motor with an energizing coil or coils connected with the generator, secondary coils in inductive relation to said energizing-coils, and energizing-coils in circuit therewith arranged in substantially the manner set forth to produce a movement or rotation of the points of maximum magnetic effect of the motor, as set forth.
6. In an electromagnetic motor the combination of independent energizing-circuits, one for connection with a source of alternating currents, the other in inductive relation to the first, whereby a

rotary movement or projection of the field-poles will be produced by the conjoint action of the two and an armature mounted within the influence of the field produced by the energizing-circuits and containing closed coils or circuits, as set forth.

Adding Machine with Keys

William S. Burroughs (1855–1898) is recognized as inventing the adding machine. Burroughs's early career experience in banking, particularly with the number of calculations required for his clerical job, motivated him to develop his concept of a mechanical way to calculate—thus, the adding machine. Following his relocation from New York to Missouri, he focused his efforts on building the arithmetic machine. Burroughs finished the device in 1885.

The original design enabled users to add numbers, but it could only save the total sum, and this lack of practicality hindered effectiveness. With the support of three businesspeople, including financial backer Thomas B. Metcalfe, the group founded the American Arithmometer Company the next year.

After spending several years refining the prototype, the company released an improved model in 1892. This practical model was produced in high quantity due to increasing demand among banks and other business. Success of Burroughs's adding machine and business venture started a line of notable technology companies from the Arithmometer Company, including Burroughs, Sperry, and Unisys. During the first half of the 20th century, Burroughs became the largest producer of adding machines.

Amalgamated Clothing Workers of America (ACWA)

One of the first unions to accept female members, the Amalgamated Clothing Workers of America (ACWA) was a leading union representing workers in the men's clothing industry during the 20th century. Known for its commitment to "new unionism" that broke away from the traditional craft union model and for incorporating progressive and socialist ideology within modern business systems, the decision to accept female members proved a significant financial breakthrough for women who worked for wages.

The ACWA was founded in 1914 in response to dissatisfaction with the conservative policies of the United Garment Workers of America (UGW). The roots of the ACWA can be traced back to the 1910 Chicago Men's Garment Workers Strike, when unskilled female workers led by Bessie Abramowitz (1889–1970) walked off of their jobs. When their skilled male counterparts soon joined them, strike numbers grew to almost 40,000. Believing it a waste of time to organize unskilled, largely immigrant workers, the UGW was unresponsive. When the strike became violent five months later, the UGW secretly negotiated an agreement and the workers returned to their jobs with no concessions. Ultimately, the failed strike laid the groundwork for future unionization; it introduced strong, new leaders and increased frustration with the strikebreaking techniques of the UGW.

Sponsors of the UGW annual convention in October 1914 denied seats to most clothing worker delegations, deeming them anarchists out to break the union. Eventually, the various clothing representatives left

the annual meeting and reconvened to discuss their desire to break away from the UGW to form their own union. The Amalgamated Clothing Workers of America was established the following December under the leadership of Sidney Hillman (1887–1946), a key player in the Chicago strikes.

The ACWA emerged with an intense campaign to unionize workers, which was highly successful in Chicago, where a series of strikes beginning in 1915 led to union presence in shops. Hillman's policy of providing support for the strikers forced the companies to relent, and most of the large firms were organized. A large push in 1916 focused on female workers, who composed more than half of the men's clothing industry.

By 1920, the ACWA included 177,000 members (66,000 women) from across the United States and Canada and held contracts with 85 percent of men's clothing manufacturers in those countries. The influx of members and successful strikes allowed the ACWA to implement member benefits such as unemployment insurance, support for the families of striking workers, educational classes in English, day care centers, banking, and insurance for its members.

The organization created a women's department under the direction of Dorothy Jacobs Bellanca (1884–1946), who won a spot on the ACWA's national board in 1916 and became its first full-time female organizer in 1917. Bellanca, at the age of 14, had served as president for her newly organized local Baltimore Button-hole Makers Union and made her mark leading a successful strike. She would later serve as ACWA vice president from 1934 until her death in 1946. In strikes in many major cities, hundreds of women picketed and were arrested and jailed, often after initiating walk-outs. Despite their efforts, women lacked day-to-day support, and the women's department was a short-lived endeavor. In response, locals in many urban areas organized woman-centric programs and discussions.

As the economy declined in the late 1920s, the ACWA struggled to maintain its membership. The organization lent money to employers in an effort to preserve jobs and attempted to connect unemployed members with available jobs. In response to racketeers demanding protection money, Hillman worked to

expel organized crime and communism in the ACWA ranks. With member loss growing, the ACWA joined the American Federation of Labor (AFL). The connection with the AFL was short-lived, however, as Hillman joined with the United Mine Workers to form the Congress of Industrial Organizations (CIO) in 1935.

During World War II, the union benefited from securing government contracts for workers producing military uniforms and parachutes. Women in particular benefited from the creation of new wartime jobs. Encouraged by their success in the postwar climate, the CIO (now including the ACWA) started Operation Dixie, a campaign to unionize Southern workers. The ACWA was one of the only organizations to send female organizers into the field—but the operation failed.

In 1952, the ACWA signed a contract covering all workers in the men's clothing industry, the first of its kind in this field. Women continued to feel ignored by the leadership, however. In Bessie Abramowitz Hillman's speech (she and Sidney married in 1916) at a 1961 Industrial Union Conference, she accused male leaders of providing only token positions for their female counterparts and encouraged women to fight for recognition.

By 1973, the ACWA included 365,000 members, with larger numbers of Latino and Asian workers joining the ranks. It continued to petition businesses throughout the 1970s up until 1990 and won many victories in large firms across the United States, including a notable partnership with Levi Strauss in 1994.

The organization merged with the Textile Workers Union of America in the South, forming the Amalgamated Clothing and Textile Workers Union (ACTWU) in 1976, and it added the United Hatters, Cap and Millinery Workers International Union in 1983. The ACTWU then merged with the International Ladies' Garment Workers' Union, creating the Union of Needletrades, Industrial and Textile Employees in 1995, and, in 2004, that union merged with the Hotel Employees and Restaurant Employees Union to become UNITE HERE—which continues to represent workers throughout the United States and Canada. In 2009, many of the members split from the union and formed Workers United.

American Telephone and Telegraph Company (AT&T)

For most of the 20th century, American Telephone and Telegraph Company (AT&T) was the largest corporation in the world. In 1885, National Bell Telephone Company (NBTC) established AT&T to provide the first nationwide long-distance network. Deeming it a monopoly, the U.S. Department of Justice broke up AT&T in 1984. Throughout its history, AT&T built most of the U.S. telephone system, and the company's technological innovations served as a standard for the world's telephone industry.

Patents of various telecommunication innovations gave NBTC a tremendous advantage over its competitors. NBTC went through several transformations and name changes until AT&T became NBTC's parent company in 1899. Like NBTC, for much of its history, AT&T functioned without significant competition. In spite of the firm control that AT&T held over the telephone industry, the company's leadership was not content with stagnation. One way that AT&T executives sought to remain ahead of competitors was through continual technological innovation. For example, the company rolled out the first coin-operated public telephone (1889) and four-party service (1891). The company also patented the first automatic dialing system in 1891.

The installation of long-distance lines was expensive, and AT&T (incorporated in 1885) often sold

bonds to raise the needed funds. In 1892, the company opened a long-distance telephone line from New York to Chicago. The next year, it opened lines from Boston to Chicago and from New York to Cincinnati. Nationwide, the number of telephones using AT&T service jumped from 240,000 in 1892 to 800,000 in 1899. Unfortunately, by the late 1800s, many of its patents had expired. To keep costs down and maximize profits, AT&T formed alliances with many companies from around the world that produced low-cost telephone equipment. By 1900, AT&T had assets totaling \$120 million.

By the early 1900s, a multitude of competitors collectively gained 51 percent of the telephone market. However, AT&T continued to hold a monopoly over long-distance service. During the late 1800s, AT&T had developed a reputation for poor customer service. However, competition convinced company executives to adopt a new business philosophy that balanced profits with customer satisfaction. Additionally, continued innovation was seen as the best way to regain the majority of the market. During these years, AT&T began using the loading coil, a small electronic device that allowed for the use of smaller-diameter wires. The new technology made it possible, for the first time, to use long-distance underground cables.

By 1906, long-distance underground cables connected New York and Philadelphia. Although underground cables had lower transmission losses than overhead cables, long-distance signals remained weak and difficult to hear. To address this problem, in 1912, AT&T implemented the vacuum-tube repeater. During World War I (1914–1918), AT&T supplied domestic and foreign military telephone service under the leadership of the U.S. government. Military leaders placed AT&T under a branch of the U.S. Postal Service, and there was talk about making the move permanent. However, after the war, support faded for government ownership of AT&T. By 1918, AT&T had 10 million phones in service.

In 1921, AT&T installed the first undersea cable connecting Key West, Florida and Havana, Cuba. To continue to promote innovation, AT&T created Bell Labs. Although Bell Labs's ventures were mostly focused on improving telephone technology, research and development included a wide range of

technological interests. For example, in 1929, engineers demonstrated a prototype of the color television. Due in great part to friendlier customer service, telephone innovations, and infrastructure expansion, during the 1920s and 1930s, AT&T secured a much greater hold on the telephone market. Although many smaller independent companies existed, most of them had no choice but to connect their phones to AT&T lines.

By 1939, AT&T controlled 83 percent of all U.S. telephones and 98 percent of long-distance wires. During World War II (1939–1945), there was a great demand for long-distance communication. More than a million new telephones were installed in 1941 alone. In 1948, Bell Labs created the transistor, which replaced the vacuum tube in telephone networks. Compared to vacuum tubes, transistors were less expensive and much smaller. In 1956, Bell Labs was awarded the Nobel Prize for the introduction of the transistor, which had applications far beyond telephone use. Bell Labs developed cellular phone wireless technology (1947), the computer modem (1957), and communication satellites (1962) that orbited the earth and facilitated worldwide telephone communications. In 1965, the development of electronic switching systems permitted a vast increase in telephone traffic and also set the stage for later Internet traffic.

By the 1980s, AT&T employed more than 1 million people. The federal government ruled that AT&T was a monopoly and ordered that it be dismantled. In 1984, when it was broken up, the company's assets totaled about \$155 billion, which was more than the assets of General Motors, Mobil, and Exxon combined. Even though AT&T's share of the long-distance market began to steadily decline after the breakup, the company still held a great part of the market. Its share of long-distance telephone service based on minutes of use were 85 percent in 1984, 80 percent in 1985, 75 percent in 1986, and 70 percent in 1988.

As early as the 1980s, AT&T began focusing on computer and Internet technologies. In the 2000s, AT&T expanded its international and domestic wireless streaming technology services. After purchasing the Mexican carrier Iusacell and the Mexican wireless business of NII Holdings, the company combined the two to form AT&T Mexico in 2014. Domestic

expansion included the purchase of Time Warner in 2016 and DirecTV in 2017. By 2018, AT&T was planning to launch an innovative cable TV–like service through its broadband network.

Asphalt

Though the word "asphalt" properly means any sticky residue of petroleum, it is most commonly used to describe a petroleum distillation combined with mineral aggregate (gravel) that is used to surface roads. Edward J. de Smedt invented modern road asphalt in 1870. Asphalt is ubiquitous in contemporary America, covering 94 percent of all road surfaces.

Before the invention of asphalt, road builders and civil engineers struggled to develop an easy-to-use, durable road surface. Indeed, one of the reasons for the early 19th-century popularity of railroads and canals lies in the poor condition of American roads at the time. Poor roads translated to slow transportation of goods and people. The most effective roads were made of layers of broken rocks, the depth of which was calculated against the road's weather and traffic. Rock proved difficult to find in some areas and heavy to move in all areas, and the resultant roads were far from smooth.

In the late 1860s, Edward de Smedt immigrated to the United States from Belgium. He patented asphalt, more popularly called "French asphalt cover," in 1870

while employed by Columbia University. He first applied it to a Newark, New Jersey, road. When that experiment proved successful, he laid his first road cover in New York's Battery Park in 1872.

While asphalt exists naturally, most notably in the La Brea Tar Pits in Los Angeles, California, the bulk of asphalt is manufactured from crude petroleum oil. Fuel and motor oil is first extracted from the naturally occurring oil, and the substance remaining, sometimes called tar, becomes asphalt. Asphalt is an affordable, durable road surface, though it is not environmentally friendly or sustainable. In 21st-century America, asphalt covers most parking lots and roads. It is also used on airport runways and on the driveways of private houses. Asphalt, or roof tar, is also applied to paper used in building roofs.

Aspirin

Aspirin (acetylsalicylic acid or ASA) is a white, crystalline substance derived from salicylic acid. While modern aspirin is synthetically produced, salicylic acid occurs naturally in many plants, including the willow tree, from which it gets its chemical name (the Latin name for the willow plant is *salix*).

The use of willow bark and leaves as a treatment for illnesses is believed to go back about 3,000 years. It is mentioned in the Ebers Papyrus, an Egyptian medical scroll of herbal knowledge dating to around 1550 BC. Hippocrates, the Greek physician who lived from about 460 to 377 BC, also wrote that willow leaves and bark relieved pain and fevers.

However, it wasn't until hundreds of years later that more attention was brought to willow bark's effects. In 1757, an English clergyman, Edward Stone,

essentially rediscovered its properties. He happened to taste some of the bark (no one is quite sure why) and noticed that its bitter flavor was quite like that of the bark of the cinchona tree. Cinchona contains quinine, which is used as a treatment for malaria.

Stone was excited about the possibility of finding a local plant that could treat malaria, because the tropical cinchona tree only grew in South America, making the bark expensive and hard to get. He dried some willow branches and ground them into a powder, giving it to family and friends who were suffering from fever and chills. In 1763, he wrote a report on how it had benefited 50 people to whom he'd given it. Their fever, chills, aches, and pains had disappeared, at least temporarily.

In the 1800s, as scientific advances began to speed up the understanding of the actions of naturally occurring drugs, researchers across Europe started to try to isolate the active ingredient responsible for their healing effects. German pharmacy professor Joseph Buchner was the first to isolate salicylic acid in 1828, in the form of bitter yellow crystals that he called "salicin."

In 1829, French chemist Henri Leroux improved on Buchner's process, and in 1838, Italian chemist Raffaele Piria refined it even further, calling his more potent isolate "salicylic acid." Reports of the beneficial properties of salicylic acid spread quickly, and demand grew. Chemistry professor Hermann Kolbe worked out its chemical structure and succeeded in making it synthetically in 1859. This allowed salicylic acid to be produced on an industrial scale, and by 1874, a factory in Dresden was able to offer it for sale at a tenth of the price of the natural substance extracted from willow bark.

There was a problem with salicylic acid, however. It was extremely bitter tasting and very corrosive to the mouth, throat, and stomach—so much so that some patients refused to take it, preferring the less potent salicin crystals. It would take the work of a young chemist 23 years later to solve the problem.

That chemist, Felix Hoffmann, was born in 1868 in Ludwigsburg, Germany. After graduating from Munich University, he was hired by Friedrich Bayer & Company in 1894 as a pharmaceutical chemist. Bayer, founded in 1863 as a dye company, was expanding

beyond its initial ambitions and was assembling a team to discover and mass-produce drugs.

There are conflicting stories about how Hoffmann came to work on the project. Some sources, including Bayer & Company itself at one time, say that Hoffmann took up the challenge on his own initiative because his father suffered from painful rheumatism and found salicylic acid too hard on his stomach.

Newer research, however, has shown that it is much more likely that he was assigned the project by his supervisor, Arthur Eichengrün, who thought a compound with fewer side effects could be commercially successful. What is agreed upon is that on August 10, 1897, Felix Hoffmann wrote in his laboratory journal that he had created a substance—acetylsalicylic acid, or ASA—that neutralized the chemical element of salicylic acid that was responsible for its most corrosive effects.

Curiously, the new drug was initially rejected by the head of Bayer's testing department due to the erroneous belief that it was bad for the heart; large doses of salicylic acid could cause rheumatic fever patients' hearts to race, and it was his feeling that this drug would be no different.

Arthur Eichengrün, upset by the rejection, sent some samples of ASA to Felix Goldmann, a Bayer representative in Berlin. Goldmann gave them to doctors there and received glowing reports on its effectiveness and palatability. It was sent into testing again and approved for production.

The new drug then needed a name. The *a-* in aspirin comes from the process that Hoffmann used to create it: acetylation. The middle letters—*spir*—come from *Spiraea*, a biological genus of shrubs that contain natural sources of salicylic acid. The *-in* was added to make the word easier to say.

Production of aspirin started in July 1899. Initially packaged as a powder in glass jars, parcels of it were sent to hospitals and pharmacists across Europe as its manufacturer touted the drug's reduced gastric irritation and analgesic effects. Within 15 years, aspirin became one of the most widely used drugs in the world. Due to a quirk in German patent laws, however, Hoffmann made no money from his discovery.

Recent research has revealed that aspirin treats more than fever and pain. It has been found to reduce

the incidence of blood clots and is often prescribed to prevent heart attacks and strokes. Aspirin may also prevent certain types of cancer. Today, four out of five people with heart disease use aspirin regularly, according to data from a 2006 Centers for Disease Control and Prevention study.

Barbed Wire

Barbed wire was invented in the 1800s to prevent cattle from wandering the vast American plains. During World War I, however, it contributed to the deadlock on the Western Front, and tangles of wire came to symbolize the industrialized nature of the war and the inhumanity of its violence.

Humans in antiquity made wire to make jewelry and later used it for practical purposes such as the manufacture of pins and wool cards (brushlike devices for combing wool fleece). Demand for wire increased in the industrial era, especially after the invention of the telegraph. During the American Civil War, both sides used telegraph wire for military purposes. In addition to using it in communications, soldiers strung telegraph wire between trees, stumps, and rocks to trip up attackers and break up formations. The tactic was moderately successful but failed to have a major impact on military planning and strategy.

In 1874, a 60-year-old Illinois farmer, Joseph F. Glidden (1813–1906), patented the first successful

Joseph Glidden applied for a patent on barbed wire fences in 1874, even though Lucien Smith had earned one in 1867. The Barbed Wire Patent court case that followed dealt with questions of first to file and scope of novelty. Glidden won the case. (National Archives)

barbed wire. He recognized that the lack of trees on the American plains made it impossible to control livestock with traditional wooden fences. Glidden used a coffee grinder to make barbs that he placed at regular intervals on a wire. Another wire was then twisted with the original strand to keep the barbs from slipping. The result was a lightweight fencing material that could be used anywhere. The demand for barbed wire was coupled with the simultaneous development of cheaply produced steel. In 1901, the United States produced over 135,000 tons of barbed wire, and the open range was no more.

Military leaders soon recognized barbed wire's value in defensive positions. In 1888, British military manuals recommended its use. During the Spanish-American War, American troops used strands of barbed wire to defend their camps from surprise Spanish attacks. One of the most controversial uses of the fencing materials was during the South African (Boer) War. During that conflict, British forces used lines of blockhouses and barbed-wire fences to cut off Boer forces from their civilian supporters. Both black and white South Africans were herded into concentration camps and fenced in. In the Russo-Japanese War of 1904–1905, Russian forces defending Port Arthur used multiple lines of barbed-wire obstacles to blunt Japanese assaults.

The Russo-Japanese War was a rehearsal for World War I in many ways. By November 1914, warfare on the Western Front had settled into a deadlock of trench lines from Switzerland to the English Channel. Specially produced military barbed wire, with larger barbs, was strung in thick belts by both sides to protect the trenches. When coupled with machine guns, the wire was an almost impenetrable obstacle. Special pickets to hold the wire consisted of two flat pieces of steel, formed into an L shape. Slots on the side held the wire in place. The pickets were either driven into the ground or had a screw attachment for silent emplacement. Attempts to cut the wire with artillery shells were usually unsuccessful. The flexible wire either sprang back to its original position or blew into the air, landing in a more impenetrable mess than before. Infantry that attacked enemy trenches were often stopped by wire with no gaps and cut down by machine guns.

Attacking infantry units had to force their way through the wire. Wire cutters were used to create gaps, but it was slow work and usually attracted enemy fire. Grappling hooks were sometimes used to drag the wire out of place, with limited success. Other methods included covering the wire with boards, blankets, or human bodies to allow soldiers to run across. Explosives, such as Bangalore torpedoes (explosive devices placed at the end of a long, expandable tube), were sometimes used to blow holes in the wire. The need to overcome the combination of barbed wire and machine guns led directly to the invention of the tank by the

Allies. Tanks were able to crush the wire or drag it out of the way of following infantrymen.

Barbed-wire obstacles became one of the most enduring images of trench warfare. Small parties of men slipped out of the trenches at night to put up or repair their own wire or to cut the enemy's. In the aftermath of attacks, dead or seriously wounded soldiers were often left on the wire. Their bodies, slowly decomposing, became one of the many horrors of the war.

Primary Document: Excerpts from an Article on Joseph F. Glidden and the Barb-Wire Industry (1884)

In its January 5, 1884, issue, The Prairie Farmer: A Weekly Journal for the Farm, Orchard and Fireside published an article summarizing the life of Joseph F. Glidden, the inventor of barbed wire, and describing the current state of the barbed-wire industry. The article clearly indicates the great impact that the invention of barbed wire had on farming and ranching in the United States. Reproduced here are excerpts from that article.

Joseph Farwell Glidden, "the Father of the Barb-Wire Business" of this country, is now a hale and hearty man of seventy-one. He was born at Charleston, N.H. When about one year old the family came West, to Clarendon, Orleans county, New York, and engaged in farming. The young lad, besides mastering the usual branches taught in the common schools, gave some time to the higher mathematics and Latin, intending to take a college course, an idea that he finally abandoned. He taught in the district schools for a few terms. In 1842 he came to Illinois and purchased a quarter section of land a mile west of what is now the site of the pleasant and prosperous town of DeKalb. With the exception of three years his life since then has been passed upon this farm and at DeKalb. He has from time to time added to his homestead, his farm now embracing 800 acres. His land is

under excellent cultivation, a considerable portion of it having been thoroughly tiled, and his farm buildings are first-class. Mr. Glidden has been twice married. Two children were born of the first union, both dying in infancy. By his second marriage he has one daughter, now the wife of a Chicago merchant.

Mr. Glidden has held several local offices of trust and honor and enjoys in a marked degree the esteem and confidence of the citizens of his neighborhood and county. The rapid accumulation of property of late years, through his barb-wire patents and business, gave him the means to gratify his feelings of public spirit, and in consequence the town of DeKalb has benefited greatly at his hands. Its leading hotel and many other buildings are the work of his enterprise. Mr. Glidden has never lost the simple manners of the farm. He is unostentatious, quiet, genial, and at his hotel makes everybody feel as much at home as though enjoying the hospitalities of his private house. His kindly, firm, and intelligent face is well shown in the accompanying portrait, though, as is usually the case, the hand of the artist has touched his features more lightly than has the hand of time.

Few names are now more widely known among the land holders of the country than that of Joseph F. Glidden, the unpretending gentleman whose life we have briefly sketched. It was his fortune to seize upon

an idea, and push it to development, which has not only given him fame and fortune, but which has enriched many others and saved many millions of dollars to the farmers of America. He has not only founded a mammoth industry, but he has revolutionized an economic system of the world. By his ingenuity and perseverance the fencing system of a pastoral continent has been reduced to a minimum of expense and simplicity. Not that he individually has accomplished all this, but as the patentee of the first really successful barb-wire fence, he laid the solid foundation for it all.

The first application for a patent for the Glidden barb was filed October 27, 1873. For some weeks previous to this date Mr. Glidden had had in his mind the idea of a barb of wire twisted about the main wire of the fence, leaving two projecting points on opposite sides. He made some of these by hand with the aid of pinchers and hammer. He strung two wires between two trees and twisted them together with a stick placed between them. A pair of cutting nippers was the next addition to his "kit" of tools. His next means for twisting the two wires together was the grindstone—attaching one end of the wire to shaft and crank, the others being fastened to the wall of the barn. And here, as in most things great and small in this world, woman furnished the motor power. The strong arm of the good helpmeet, Mrs. Glidden, turned the grindstone that twisted the first wire that made the first Glidden barb fence that kept stock at bay in Illinois or the world. Then followed a device for twisting and barbing, and the application of horse power. Business expanded, and steam took the place of the horse, and inventive genius modified and improved the entire machinery, it being estimated that at least the sum of \$1,000,000 has been expended in bringing the machinery for barb-wire making to its present state of perfection.

At about the same time that Mr. Glidden was wrestling with his ideas and devices, Mr. I.L. Ellwood was experimenting to accomplish a like result with a thin band of metal, the barbs cut and curved outward from the strip. In the meantime Mr. Glidden had put up a few rods of his hand-made barb-wire along the roadside at his farm. And here again the good genius of woman enters upon the scene. One Sunday Mr. Ellwood and his wife were driving along this road

and attracted by the wire fence stopped to examine it. Mrs. Ellwood, much to the chagrin of her husband, remarked: "This seems to me a better device than your own, don't it to you?" It did not then, for the remark disappointed and angered him. But it set him to thinking and before the next morning he was of the same opinion. The two men meeting the next day it did not take long to compromise and unite. Mr. Ellwood dropped his own plans and accepted a half interest in the Glidden patents, and assumed the management of the business end of the concern, in which position he developed ability and tact possessed by few business men in this country.

The barb-wire fence met an unexpected and general demand. We know of few things like it in the history of manufactures. From [Pg 2] this small beginning, scarce ten years ago more than fifty large establishments are now turning out this wire to meet an ever insatiate demand. The establishment of I.L. Ellwood (making the Glidden wire) at DeKalb is the most complete and extensive of them all. The building is 800 feet in length, and is supplied with about 200 machines for twisting and barbing the wire. It gives, when running full force, employment to about 400 men, and turns out a car-load of wire each hour for ten hours per day, on an average, though this amount is considerably increased at certain times of the year. These figures, though not given us by Mr. Ellwood, we are satisfied do not overstate the production of this one factory. The progress of the barb-wire industry of the whole country is shown by the following record of the past nine seasons. In

1874 there were 10,000 lb made and sold.
 1875 there were 600,000 lb made and sold.
 1876 there were 2,840,000 lb made and sold.
 1877 there were 12,863,000 lb made and sold.
 1878 there were 26,655,000 lb made and sold.
 1879 there were 50,337,000 lb made and sold.
 1880 there were 80,500,000 lb made and sold.
 1881 there were 120,000,000 lb made and sold.
 1882 there were about 180,000,000 lb.

The record for 1883 is not yet made up, but will probably show a corresponding increase.

In 1876 Mr. Glidden disposed of his half interest in the concern of Glidden & Ellwood to the

Washburn & Moen (wire) Manufacturing Company, of Massachusetts, receiving therefor \$60,000 in cash and a royalty on the future goods manufactured, Mr. Ellwood retaining his interest. The new concern began the purchase of prior unused and conflicting patents involving itself in extensive litigation, but, sustained by the courts, soon gained control of almost the entire barb-wire business of the country.

Nearly all wire-making companies are now running under license from the parent concern.

Source: “Joseph F. Glidden: The Barb-Wire Industry—Some Facts in Its Early History Not Generally Known—Its Growth.” *The Prairie Farmer: A Weekly Journal for the Farm, Orchard and Fireside*, Vol. 56: No. 1, January 5, 1884, 1–2.

Batteries

Batteries are relatively small devices for the conversion of chemical energy into electricity. They allow for the portability of devices that require a permanent electrical connection.

A battery consists of one or more cells (electrodes) called “cathode” and “anode”; these are the positive and negative terminals respectively. The terminal’s position depends on the direction of electricity flow. There is a liquid called an “electrolyte” between the electrodes that serves as the connection that allows the transfer of ions between them. The type of electrodes and electrolyte used depends on the rating of the battery—how much voltage and amperage it is designed to produce. The time that a battery runs depends on the size of the electrodes, since there is a finite number of ions that can be transferred between them.

The first battery was invented in 1800 by Italian inventor Alessandro Volta. There have been many improvements in them since. The most important is in the size, which has allowed technology to be more portable than ever. They are used in a wide range of devices such as small wristwatches, cell phones, portable computers, and hearing aid devices as well as airplanes, cars, and boats. There are two main types of batteries in current use: primary and secondary.

Primary batteries are the most common. They are used for low-current devices and are meant for one use only, because the chemical reactions that produce electricity in them are hard to reverse. The only possible way to reuse these batteries is to replace the

electrodes, but such a task is hard to do for the average person. These batteries are disposed of after a single use. Secondary batteries are commonly known as “rechargeable batteries.” They require charging before they are first used, but once they have been drained of all their current, they can be recharged by applying current to them, reversing the discharging process.

Batteries are on the verge of changing the automotive industry. Tesla Motors has taken the lead in that respect, though many other automotive companies have introduced electric cars utilizing batteries. Electric cars, from the Honda Prius to the Nissan Leaf, use battery technology to replace petroleum-fueled combustion engines.

In the 21st century, batteries have become increasingly environmentally unsustainable. Toxins in batteries poison the environment. This is a particular problem for electric car batteries. Rechargeable batteries ameliorate this problem, but the problem remains.

Bee Smoker

Moses Quinby invented the modern bee smoker in 1875. He was also the first American to keep bees for commercial purposes. Born in 1810, Quinby became known as the “Father of Practical Bee Keeping” for his astute observations on bee behavior and needs. Quinby believed that his knowledge should be freely shared. To that end, he wrote *Mysteries of Bee-Keeping Explained* in 1853. The same year, Lorenzo Langstroth published his book *Langstroth on the Hive and Honeybee*. The two books became the foundation of commercial beekeeping in America. In addition to inventing the first bee smoker, Quinby also developed the first centrifugal extractor for removing honey from wax combs.

Beekeepers have long known of the calming effect of smoke on bees, though until Quinby invented the smoker, the ability of a beekeeper to effectively harness this soporific effect was limited. Bee smokers are generally small enough to be handheld. They consist of a chamber and spout, not unlike those of a coffee pot or teapot, attached to a bellows. Beekeepers start a fire inside the smoker’s body, fueled by twigs, leaves, cotton, and more, and close the lid so that the fire smolders, producing smoke. The bellows are then employed to pump smoke from the spout onto the bees. The smoke does not harm the bees but makes them lethargic and of less danger to the beekeeper, who must not only have access to the bees’ honey but

must also on occasion check the hive for sickness or pests, feed the bees, and observe the queen’s condition.

The mechanism whereby smoke makes bees “sleepy” was not understood until the 20th century. Guard bees emit pheromones that alert other bees to danger and send them into attack mode; smoke masks these chemicals. Smoke also sends the colony into a feeding frenzy, as bees consume honey so that the hive can be rebuilt after a fire. Bees with full stomachs cannot effectively sting, because their abdomens are too distended to allow them to flex for that.

Today, beekeeping supply houses sell easy-to-use materials for bee smokers. Pulp paper blocks and compressed cotton wads are among the most popular. Bee smokers come in a variety of sizes and shapes, but all share the same basic anatomy as Quinby’s original design.

Contemporary American beekeeping is a multi-million-dollar industry (\$304 million in 2017). Beekeepers collect and market not only honey but also royal jelly, queen bees, pollen, and venom.

Jackson, Paul. 2014. *Smoking Allowed—A Pictorial Past of Honey Bee Smokers in the United States*. London: Northern Bee Books.

Primary Document: Excerpt on the Use of a Bee Smoker from Moses Quinby’s *Mysteries of Bee-Keeping Explained* (1853)

*Moses Quinby was one of the first commercial beekeepers in the United States. In 1853, he wrote *Mysteries of Bee-Keeping Explained*. The following excerpt from it deals with the soporific effect of smoke on angry or swarming bees and suggests a model for a handheld bee smoker to pacify them. Quinby wrote his book in easy-to-read and exceptionally engaging language.*

THEIR MANNER OF ATTACK.

I must disagree with any one who says we always have warning before being stung. I have been stung a few times myself. Two-thirds of them were received without the least notice—the first intimation was the “blow.” At other times, when fully determined on vengeance, I have had them strike my hat and

remain a moment endeavoring to effect their object. In this case, I have warning to hold down my face to protect it from the next attempt, which is quite sure to follow. As they fly horizontally, the face held in that position is not so liable to be attacked. When they are not so thoroughly charged with anger, they often approach in merely a threatening attitude, buzzing around very provokingly for several minutes in close proximity to our ears and face, apparently to ascertain our intentions. If nothing hostile or displeasing is perceived, they will generally leave; but should a quick motion or offensive breath offend them, the dreaded result is almost sure to follow. Too many people are apt to take these threatening manifestations as positive intentions to sting. When these things can be quietly endured, and at the same time leave their vicinity, it generally ends peaceably. They never make an attack while away from their home in quest of honey, or on their return, until they have entered the hive. It is only in the hive and its vicinity that we expect to meet this irascible temperament, which should not be allowed, or at least may be subdued in a great measure, if not entirely, by doing things in a quiet manner, and, by the use of tobacco smoke. Any person having the care of bees should go armed with this powerful weapon. As bees are not much affected with smoke, while flying in the air, but will have their own way, we must take them in the hive as the place to teach *them* a proper deportment!

Those who are accustomed to smoking will find a pipe or segar very convenient here. But such as are not would do better, perhaps, not to learn a bad habit. I will therefore give a simple substitute.

SMOKER DESCRIBED.

Get a tube of tin about five-eighths of an inch diameter, five or six inches in length; make stoppers of wood to fit both ends, two and a half or three inches long; with your nail-gimlet make a hole through them lengthwise: when put together it should be about ten inches. The ends may be tapered. On one end leave a notch, that it may be held with the teeth, which is the most convenient way, as you will often want to use both hands: it is also always ready, without any trouble to blow through, and also to keep the tobacco burning. When ready to operate, fill the tube

with tobacco, ignite it, and put in the stoppers; by blowing through it you keep the tobacco burning while the smoke issues at the other end.

EFFECT OF TOBACCO SMOKE.

We can now subdue these combative propensities, or render them harmless; turn their anger to submission, and make them yield their treasures to the hands of the spoiler without an effort of resistance! When once overpowered, they seem to lose all knowledge of their strength, and no slave can be more submissive! After the effects of the smoke have passed off, their former animosity will return. Should any resentment be shown on raising a hive, blow in the smoke; they immediately retreat, “begging pardon.” After a few times, they learn “it’s no use,” and allow an inspection. If you wish to take off a box, raise it just enough to blow under the smoke; there is no trouble; you can replace it with another; the bees are kept out of the way with a little more smoke, *and no anger created about it to be remembered*. Those in the box are all submission; they can be carried away and handled as you please, without a possibility of getting them irritated, until they once more get home, and then are much more “amiable” than if the box had been taken without the smoke. They seem to forget, or do not realize anything of the transaction. When bees are to be transferred to a new hive, it is unnecessary to be so very particular about the escape of a single bee; no fears need be entertained of such as get out. In driving, the loud humming indicates their submission; the upper hive can then be safely raised at any time. After being thus driven out, they may be pushed about with impunity, and still be quiet! In short, by using smoke on all occasions where they would be likely to be disturbed without it by our meddling with them, it has a tendency to keep dormant their combative propensities. When these have never been aroused, there is much less danger from their attacks while walking or looking among them. Any one wishing further proof, I would recommend the experiment of managing one year with smoke, and the next without.

Bell, Alexander Graham (1847–1922)

Scottish-born scientist, inventor, engineer, and educator Alexander Graham Bell is credited with designing and constructing the first practical telephone.

Bell was born on March 3, 1847, in Edinburgh, Scotland, to Alexander Melville Bell, an expert in phonetics who taught elocution to the deaf through a system dubbed “Visible Speech,” and Eliza Grace Symonds Bell, an accomplished pianist who was herself nearly deaf. He also had two brothers: Melville James Bell (1845–1870) and Edward Charles Bell (1848–1867). His early education consisted of being homeschooled by his mother, followed by three years of formal education—one year in a private school, and two at Edinburgh’s Royal High School. During this time, his aptitude for observation and innovation became apparent. At age 12, he devised a homemade device for quickly husking grain after watching the process in a grain mill while playing with a friend. At age 16, he joined the legacy of his father and grandfather as a “teacher of the deaf”—a title he preferred to be known by—and oversaw his father’s operations in London.

In 1870, the Bell family immigrated to Brantford, Ontario, Canada, after both of Alexander’s brothers died of tuberculosis. At that time, the elder Bell’s Visible Speech system caught the attention of Sarah Fuller, who ran the Boston School for Deaf-Mutes and requested that he apply it to her students. He instead sent Alexander, who moved to Boston in 1871 to apply his father’s system. He found success as a teacher to the deaf and went on to teach at the Clarke School for the Deaf in Northampton, Massachusetts, and the American School for the Deaf in Hartford, Connecticut. While on this circuit, he met his future wife, Mabel Hubbard (1857–1923), a student who had become deaf at age five due to scarlet fever, who was also the daughter of Gardiner Greene Hubbard (1822–1897), cofounder of the Clarke School and Bell’s future financial backer. In 1872, he achieved the position of professor of speech and vocal physiology at the Boston University School of Oratory.

In the early 1870s, Bell began conducting experiments in two-way telegraphy. At the time, the telegraph system was the dominant mode of long-range

communication but was constrained to the dispatch and reception of a single message at a time through a single wire. There was developing fervor to discover a “harmonic telegraph” capable of several messages over several frequencies down a single telegraph wire. Examples from Bell’s contemporaries included Thomas Edison’s (1847–1931) “quadruplex,” which could send 4 messages simultaneously, while Elisha Gray (1835–1901) managed 10. However, all of these laboratory-successful designs proved unreliable in service and thus became practically invalid. Bell received financial backing from Hubbard and businessman Thomas Sanders but soon gained a new ambition: to transmit the human voice across the distance of a telegraph.

Between 1874 and 1875, Bell was joined by electrician Thomas Watson (1854–1934), originally hired to refocus Bell on the aim of his original investment but who soon became the engineering analogue to Bell’s problem-solving ingenuity. Bell’s apparatus was based on the phonautograph, the earliest sound-recording device, and utilized make-break current interrupters driven by vibrating steel reeds or tuning forks. These sent the interrupted current to a distant receiving electromagnet that caused a second reed to vibrate, creating a pattern of vibrations that could be translated into the same voice pattern as transmitted. In the final stages of his experiments, Bell used a water transmitter to conduct the vibrations: the vibration of a diaphragm causes a reed suspended in water—mildly acidified to ensure conductivity—to vibrate, which varies the electrical resistance in the water and causes alternating current in the circuit, translated into voice patterns at the receiver. Bell and his benefactors filed a patent for the apparatus, which was granted on March 7, 1876. Three days later, on March 10, Bell successfully transmitted a full sentence through his apparatus to Watson in an adjacent room, which has been famously recounted in the lab notes and journals of the two scientists as: “Mr. Watson—come here—I want to see you.” According to legend, Bell spoke these words after accidentally spilling a jar of transmitting fluid and called Watson over to help him clean it up, however, it is more likely that the first transmission was entirely planned. Bell had thus succeeded in surpassing the

endeavor for harmonic telegraphy by creating the world's first serviceable telephone.

Bell continued to refine his device for longer distances before demonstrating it publicly for the first time at the Philadelphia Centennial Exhibition, which included such witnesses as Scottish physicist Sir William Thompson and Emperor of Brazil Dom Pedro II. Hubbard assembled the investors necessary to begin the Bell Telephone Company in July 1877, for which Bell acted as technical advisor until his withdrawal from interest in telephony. At the time of the company's founding, Bell married Hubbard's daughter Mabel, and the two would go on to have four children: two elder daughters and two young sons who both died in infancy. Controversy erupted, with numerous claims by competing inventors of their own development of the telephone before Bell. Foremost was Elisha Gray, who claimed that Bell had stolen his idea of using a water transmitter to move the reed/tuning fork in the apparatus. Bell did admit to using the water transmitter for his proof-of-concept experiment but never applied it to public demonstrations or commercial ventures. The Bell Company would face over 550 court challenges over 18 years, some of which reached the Supreme Court of the United States. None were successful. In 1915, Bell inaugurated the first transcontinental telephone call, again to Thomas Watson.

In addition to the telephone, Bell was known to have held around 30 patents: 18 alone, 12 with collaborators. He opened the Volta Laboratory in 1880 to investigate flight. In 1907, he began the Aerial Experiment Association with Glenn Curtis, where he pioneered other inventions: the AEA *Silver Dart* became

the first powered flight in Canada, and he developed the hydrofoil *HD-4* with engineer Casey Baldwin (1882–1948) and Italian inventor Enrico Forlanini (1848–1930), which achieved a world record for its vessel class. Bell used his wealth from the Bell Company to finance the journal *Science* and the National Geographic Society, of which he served as second president after the death of founder and first president Gardiner Hubbard. Bell helped to tailor the society's publication for public accessibility by using illustrations, an unthinkable innovation at the time.

Alexander Graham Bell died on August 2, 1922, at age 75 of complications from diabetes. The entire North American telephone system was shut down in tribute for a full minute during his funeral. The Bell Telephone Company would go on to become the American Telephone and Telegraph Company (AT&T).

Primary Document: Letter of Alexander Graham Bell to His Parents Describing His Idea for the Telephone (1874)

In 1874, Alexander Graham Bell was in a race with Elisha Gray to develop and patent an acoustic telegraph—a device to transmit sound, including the human voice, telegraphically. In a letter to his parents, Alexander Melville Bell and Eliza Symonds Bell,

and his sister-in-law, Carrie Bell, written on November 23, 1874, Bell mentions the competition from Gray and the need to obtain a patent; he also describes his idea for the sound transmission apparatus he is developing. Bell asks his parents to save the

letter as a record of his idea and when he had it. Bell's letter is reproduced here.

Salem to Boston
Monday Nov. 23 '74
Dear P. M. & C.

Mr. Hubbard on going down to Washington found that Mr. E. Gray instead of filing a caveat had applied for a patent on his invention—so that a caveat would not protect me from him.

A caveat only protects from those taking a patent after I file the caveat.

Under these circumstances Mr. Hubbard decided not to file mine as it might injure our case by exposing our dates—to Mr. Gray.

He says the only course is to complete our instruments as rapidly as possible and apply for a patent when an interference will be raised between Mr. Gray & myself and then one who can prove priority will obtain the patent.

There is thus no present need of my becoming an American Citizen.

It is a neck and neck race between Mr. Gray and myself who shall complete our apparatus first. He has the advantage over me in being a practical electrician—but I have reason to believe that I am better acquainted with the phenomenon of sound than he is—so that I have an advantage there and I have at hand Prof. Lovering and Mr. Farmer as advisor in every electrical difficulty.

The very opposition seems to nerve me to work and I feel that with the facilities I have now I may succeed.

Portions of my apparatus will be ready for trial tomorrow. However we shall see.

I feel that I shall be seriously ill should I fail in this now I am so thoroughly wrought up.

An idea that I have scarce dared to breathe to anybody for fear of being thought insane I ventured cautiously to open to Mr. Farmer.

To my delight he said the theory was all right but that the difficulties of practically working the idea were such that it would take years to solve the problem practically. He advised me to publish the idea in the Philosophical Magazine after I had protected my telegraphic scheme. The idea to which I allude is an instrument by which the human voice might be telegraphed without the use of a battery at all.

Since the principle of the idea is all right I hope to be able to apply it practically to the telegraphic scheme at once so as to send messages without a battery—substituting instead a permanent magnet.

I shall describe the idea here which led me to think of the plan.

Although the plan has been in my head for a year or so, I never spoke of it so far as I remember as I was uncertain of the fundamental principle. Now that the principle is acknowledged correct I have no doubt the publication of the idea will lead to such an instrument as that I have described.

If you take a permanent magnet and place one of its poles near the pole of an electro-magnet a current of electricity is induced in the coils of the latter. When the permanent magnet is removed from the electro-magnet another current of electricity (of opposite kind to the first) is induced in the coils of the electro-magnet.

These facts have been known for years but the deduction which I have made from them is new. It is this.

If a permanent magnet is made to vibrate in front of the poles of an electro-magnet—an induced oscillating current will be produced in the coils of the electro-magnet. The oscillations of the electrical current will correspond in number and amplitude with the vibrations of the permanent magnet. Hence if we have a harp of steel bars made permanently magnetical arranged over an electro magnet; and if we have the bars tuned to minute intervals of pitch if we talk into one harp certain rods will vibrate with certain amplitudes. Their vibrations will create an electrical vibration in the live wire and will force into vibration the corresponding rods of the other harp.

This is the theory. I can never hope to work it out myself.

Mr. Farmer & Dr. Blake both pronounce it feasible.

Please keep this paper as a record of the conception of the idea in case any one else should at a future time discover that the vibrations of a permanent magnet will induce a vibrating current of electricity in the coils of an electro-magnet.

Fond love
(signed) Aleck

Berliner, Emile (1851–1929)

German-born American inventor, businessman, writer, and philanthropist Emile Berliner is best remembered for inventing the flat disc gramophone or phonograph. The company he founded as Berliner Gramophone engaged in various patent conflicts and disputes over the authorization of sales during its brief history and changed the landscape of sound reproduction, paving the way for the formation of the largest distributor of phonographs in the United States, the Victor Talking Machine Company.

Berliner was born in 1851 into a Jewish mercantile family in the city of Hanover. It was intended for him to follow his father into the mercantile profession, and he graduated from the Samsonschule in nearby Wolfenbüttel in 1865. Berliner became a United States citizen in 1881 and married fellow German immigrant Cora Adler that same year.

Throughout the 1870s, he worked odd jobs in Washington, D.C., and New York while studying and inventing in his private moments. He gained a keen interest in sound reproduction, in particular the workings of telephones and audio recording technologies. Berliner patented a “loose contact” transmitter or an early microphone while a night school student in physics at Manhattan’s Cooper Union Institute for the Advancement of Science and Art. This patent was later sold to Alexander Graham Bell’s American Bell Telephone Company, where Berliner subsequently gained employment from 1877 to 1883. While an employee at Bell Telephone, he patented a type of prefabricated flooring he called “parquet carpet.”

Berliner received his first patent for a gramophone in 1887 after some years experimenting as an independent researcher in Washington, D.C. It proved to be a significant development in the transfer and reproduction of sound. This patent combined the elements of a vibrating needle set within a round, permeable material that could transcribe onto a flat disc made originally of metal. He determined that a flat disc provided an easier and more effective surface for recording when compared to the more prevalent cylinder format. Later on, these master discs would be zinc covered by a thin layer of wax onto which the needle would proceed to scratch and imprint a sound

recording. An acid-treating process rendered the grooves of the recording stable and reproducible.

The 1890s witnessed the development of Berliner’s patents into a business venture. Despite the practical advances he made in developing sound reproduction, Berliner ultimately viewed his invention as a novelty or plaything. Due to patent limitations within the United States, Berliner’s gramophone was initially marketed by a toy manufacturer in Germany to play five-inch discs on a small, hand-operated machine. Berliner gathered investors, and in 1895, he founded the Berliner Gramophone Company, which marketed larger variants of the hand-propelled children’s toy.

The next step in improving his gramophone was the innovation of a motor capable of rotating the turntable consistently while bearing the weight of the reproducer. Berliner sought the collaboration of a machinist and engineer from New Jersey named Eldridge Johnson. Johnson devised and manufactured the wind-up, clockwork motor mechanism for Berliner’s company. He would go on to found the highly successful Victor Talking Machine Company, which controversially claimed Berliner as one of its founders.

Disagreements with Frank Seaman, who was originally granted the rights to market Berliner products in the United States, greatly limited the company’s ability to sell its products to an American audience. The company ceased operations in the United States in 1900 but continued operations in Canada. He received the John Scott (1897), the Elliot Cresson (1913), and the Franklin (1929) Medals from the Franklin Institute for his contributions to American invention.

The remainder of Berliner’s life was dedicated to further developments in the field of acoustics and air flight. In 1926, he patented a ceramic tile for walls to aid in sound amplification. He is also considered an early pioneer of the helicopter. In this capacity, he devised a lightweight rotary engine and developed the use of a vertically mounted tail rotor to counteract torque. Berliner was the president of the Gyro Motor Company, which marketed these aeronautical innovations, from 1909 to 1926. His son Henry Berliner continued research in aeronautics and founded the Berliner Aircraft Company.

Berliner was also an advocate for public health, in particular combating high mortality rates among women and children. He supported safe milk and cleanliness and penned a series of poems geared to children that were collected, illustrated, and published as *Muddy Jim*. He inaugurated the U.S. Bureau of Health Education in 1924. Berliner died in Washington, D.C. on August 3, 1929, from a heart attack.

Brooklyn Bridge

Designed by John Roebling, whose daughter-in-law, Emily Roebling, finished the job when he could not, the Brooklyn Bridge is located in New York City. Begun in 1869 and completed in 1883, the bridge is considered one of the great American engineering achievements of the 19th century. The bridge spans 486 meters, connecting the cities of New York and Brooklyn. It is the oldest steel cable suspension in the United States. The Brooklyn Bridge took 14 years to complete and, during the construction, at least 20 people died. The bridge cost approximately \$15 million to build. After the grand opening of the bridge, it became an icon of New York City.

The Brooklyn Bridge is a suspension bridge, but it uses a hybrid cable-suspension design that made it unique in its day. It is constructed of granite, limestone, and cement and thousands of steel cables. The bridge's caissons are built with storage compartments in them, famously used to store wine, food commodities, and other non-bridge-related oddities.

Before construction began, John Roebling injured one of his feet, contracted tetanus, and died. The bridge could have not been completed without the

knowledge of his 32-year-old son, Washington A. Roebling, and his wife, Emily Roebling. Washington took over as chief engineer. While working underwater on bridge caissons, Washington contracted decompression disease (the "bends"). Though officially, Washington completed the bridge construction, he only did so because his wife, Emily, took over as unofficial project manager, supervising the daily construction at the bridge site. Washington was forced to watch through a telescope as the bridge was being built. He remained paralyzed for the rest of his life.

Bridge workers earned two dollars a day. They used shovels and dynamite to clear away the mud and boulders from the river before building the two pneumatic caissons, or bridge foundations. This job was risky, as the hot, dense air gave workers headaches and itchy skin, and it also slowed their heartbeats.

The most dangerous part was working underwater in the East River. Workers (including Washington Roebling) rode in small iron containers called "airlocks." After the workers were brought up to the surface, the dissolved gases in their blood were quickly released, a disease called "caisson disease" then and "decompression sickness" or "the bends" now. Decompression sickness caused paralysis, joint pain, numbness, convulsions, speech impediments, and sometimes death. During the construction of the bridge, more than 100 workers were injured and at least 20 killed (the exact number is not known).

The Brooklyn Bridge opened to the public on May 24, 1883, though it was, at the time, called the New York and Brooklyn Bridge or the East River Bridge. President Chester A. Arthur, Mayor Franklin Edson, and Brooklyn Mayor Seth Low attended the bridge opening, as did thousands of New Yorkers. Emily Roebling was present on opening day, though her husband was honored as the bridge manager and she was not. She was the first person to cross the bridge, and today, the bridge carries a plaque in her memory.

On its opening, the Brooklyn Bridge carried the only road that connected Manhattan and Brooklyn. On the first day, a total of 1,800 vehicles and 150,300 people crossed. Six days after the opening of the bridge, there was a stampede off it after a woman fell down the stairs. People doubted the bridge's stability. To eliminate any doubts, circus showman and New York

luminary P. T. Barnum led 21 elephants over the Brooklyn Bridge.

Some engineers doubted the bridge's ability to withstand strong winds. It wasn't until the 1950s, after the collapse of the Tacoma Narrows Bridge, that the engineers decided to test its aerodynamics. They determined that the Brooklyn Bridge could withstand winds because its open truss structure supports the deck, which makes the bridge aerodynamic. Also, John Augustus Roebling accidentally designed the bridge to be six times stronger than he thought it was supposed to be. On the other hand, a contractor, J. Lloyd, discovered that the bridge is not as strong as people thought because cheaper, weaker wire had been used in its construction than intended. To compensate for the low-quality wire, bridge engineers added an additional 250 cables. They also added diagonal cables that were later rendered useless, but they were kept because they help give the bridge its iconic look.

The bridge was renovated between 2010 and 2015 after a bridge collapsed in Minneapolis. The New York City Department of Transportation spent \$508 million to rebuild and widen approach ramps, raise the bridge's clearance, replace rusty barriers, and restripe the road surface. The renovated upper deck supports bicycle and foot traffic, with over 3,500 cyclists and 10,000 pedestrians a week using the deck.

The Brooklyn Bridge became a National Historic Landmark in 1964 and a National Historic Civil Engineering Landmark in 1972. In 1993, on the 100th anniversary of the opening of the bridge, President Ronald Reagan led a formal procession of people walking across it. More recently, in May 2008, there were five days of festivities for the celebration of the 125th anniversary of the Brooklyn's Bridge opening along with a fireworks display. Today, the bridge continues to service New York and Brooklyn, carrying both automobile and foot traffic. The Brooklyn Bridge has become significant to couples who affix "love locks" to the bridge and throw the key into the water to mark their love.

The Brooklyn Bridge stands among the most iconic structures in the United States, along with other great building projects like the Empire State Building and the Golden Gate Bridge.

Camera

The camera records light and thus an image, either chemically or electronically. Early cameras were invented during the mid-1820s, with numerous improvements in the 1830s. The first cameras took still pictures, but later cameras also took moving pictures, giving birth to the film industry. The invention of the camera also opened a new world of art. Digital cameras, built into smartphones, are now a part of daily American life.

The term "camera" comes from the light phenomenon called the "camera obscura" (which means "dark chamber"). The invention of the camera came from the study of and experimentation with the camera obscura, in which light rays reflect off a surface: after passing through a pinhole into a darkened room or space, on the wall opposite the pinhole, the light creates a perfect image of what the light is reflecting off of (although upside down). The human eye receives images in a similar way. The camera obscura phenomenon was first observed and experimented with by early philosophers such as Mo Di (470–391 BCE) as is written of in his ancient Chinese text the *Mozì*. Scientists and artists such as Leonardo da Vinci and Johannes Vermeer used the "pinhole camera" to aid them with drawing and painting more proportionally accurate detail in their work.

In 1826, Frenchman Joseph Nicéphore Niépce (1765–1833) captured the oldest surviving photograph using light-sensitive bitumen. Following Niépce's death, his colleague Louis Daguerre (1787–1851)

When George Eastman invented this No. 1 Kodak camera in 1888, it sold for \$25 and was loaded for 100 exposures. The company stopped selling Kodachrome color film in 2009 as customers moved to digital photography. (Bettmann/Getty Images)

continued his work. By 1837, Daguerre had developed the first photographic process, the Daguerreotype, and in 1839 introduced it to the public. As the invention of the camera was improved upon and alternative processes were brought to the public's attention, what was involved in operating a camera became easier and more convenient. Daguerreotype studios came to many cities in the United States only a few years after the device was first announced. For the first time ever, an American could get his or her picture taken. This was in a stark contrast to the difficulty of being painted, which was a lengthy process and only for the wealthy; it also never yielded a fully true-to-life image.

Niépce and Daguerre weren't the only thinkers who hoped that the camera obscura would be another pathway, alongside painting and drawing, to create realistic, lasting images of the real world. To

mechanically capture and preserve the likeness of a sight would be a revolutionary concept that human-kind had never seen the likes of before. Thomas Wedgwood (1771–1805) of England conducted a great many experiments, but the most successful was his work with a silver nitrate coating on white leather. Though his work was groundbreaking and published in many places, all of Wedgwood's images darkened and were lost once exposed to light. This problem wouldn't be solved until a British scientist, William Henry Fox Talbot (1800–1877), used several techniques to stabilize this type of image. Within a year after Daguerre's public announcements, Talbot announced his "salted paper" process called the "calotype" that required a significantly longer exposure time and had less detail but had the capability of reproducing an image after it was captured.

George Eastman (1854–1932) brought photography to the masses with his mass manufacturing of the roll film camera that he referred to as the “Kodak” and patented on September 4, 1888. The low price and capacity to capture 100 exposures made the Kodak take off in popularity. Once used up, the device had to be sent back to the factory for processing and reloading with another roll of film. In 1900, Eastman introduced the world’s most successful and popular camera, the Brownie, with an initial price of a dollar. With its simple-to-use design, the Kodak Brownie and its later models became iconic among the public, with millions and millions sold. It was especially marketed to the young, popularizing amateur photography as a hobby. Many soldiers brought their Brownies along with them to war, and thus, some of the most important war photographs available today were captured on Brownies. George Eastman’s original vision to have photography available to the whole world had finally been accomplished. His slogan, “You press the button, we do the rest,” and his dedication to keeping his camera simple attracted the general public. This made his company wildly successful and made Kodak a leader in camera and film technology and sales.

In 1888, French inventor Louis Le Prince (1841–1890) recorded the first movie, *Roundhay Garden Scene*, on a single-lens, paper-film camera. Before his mysterious and suspicious disappearance in 1890, he had planned to patent his camera. Photography being able to capture motion was groundbreaking and as equally revolutionary as the first cameras. In the 1890s, several furthered such inventions, but the most significant were two French brothers: Auguste Marie Louis Nicolas Lumière (1862–1954) and Louis Jean Lumière (1864–1948). On February 13, 1895, the Lumière brothers patented their three-in-one machine that captured motion pictures, developed the film, and projected the pictures. In the first half of the 1900s, the movie industry took off, and going to the moving pictures became a favorite pastime of many.

In the last quarter of the 1900s, digital photography was slowly invented. Steven Sasson (1950–present), an engineer at Eastman Kodak, made the first digital camera. His prototype weighed eight pounds, took 23 seconds to capture, and recorded its images onto a cassette tape. The late 1980s saw several

companies release their first digital cameras. In 1988, the Fuji DS-1P was released, the first camera to digitally store images. By the 1990s, developments in digital photography were abundant, and Kodak created its photo CD system and developed the first camera made for journalists (sold for \$13,000). Considered the first DSLR (digital single-lens reflex), this professional digital camera system, or DCS, began the digital camera revolution, setting the world onto the gradual path from film cameras to digital ones. DSLR cameras were made for the common person in the early 2000s and, as film cameras became obsolete, Nikon and Canon dominated the digital camera market. High megapixel cameras in smartphones, which have become the people’s favorite camera, build on almost 200 years of invention and have crowned it all with the wonder of sharing your photographs with the world in seconds.

Can Opener

William Worcester Lyman invented the first rotating can opener in 1870. Lyman was a devoted American inventor from Meriden, Connecticut. His invention was the foundation for can openers that have been in use for almost 100 years.

Previous can openers were basically variations on knives, whereas Lyman’s opener was similar to a beam compass but with a razor on one end. This addition made the can opener much safer and simpler for

everyday use. Lyman's other patents involved improvements to household products like fruit canning jars with hinged lids, tea and coffeepots, hinged butter dishes, and refrigerated pitchers.

Unfortunately, Lyman's version of the can opener required that the can be pierced before it was rotated along the rim, and this inconvenience forced a renovation. In 1925, the Star Can Opener Company in San Francisco, California, improved on Lyman's design. The solution was adding a second, serrated wheel (feed wheel), which allowed a solid grip on the can edge. This innovation was so efficient that it is still in use today. Modern can openers require little maintenance and are quite safe.

Motorized can openers allow for simple and quick opening. Some require only making sure the can is secure and flicking the power switch. But Lyman's introduction of a rotational system gave the foundation for these impeccable systems. William Lyman may not be well known, but he should be, since most of his ideas were the template for many household items that we use today.

Carnegie, Andrew (1836–1919)

Andrew Carnegie, known to modern Americans more for his philanthropy than his business acumen, was an ingenious and innovative businessman whose efforts in building what became U.S. Steel revolutionized the American economic landscape, helping thrust the United States to the forefront of the world's industrial powers. For many Americans, Carnegie's life also became a symbol and a validation of the American experiment, for in his rise from immigrant to tycoon to economic statesman and ultimately philanthropist, Carnegie was seen as embodying the then-popular

concept of the American Dream. Others note that Carnegie's ruthless treatment of workers helped create an industrial system that encouraged unsafe working conditions, long work hours, low wages, and little job security, all in an effort to maximize profit for American industrialists. In this sense, Carnegie is a model for the Gilded Age "robber barons."

Andrew Carnegie was born in Dunfermline, Scotland, on November 25, 1836, one of two sons born to William and Margaret Carnegie. Carnegie's father moved from Dunfermline to Pennsylvania in 1848 after industrialization and mechanization caused the elder Carnegie, a weaver, to lose his job. Settling in Pittsburgh, William Carnegie secured a job in a cotton factory, and Andrew was hired as a bobbin boy. Beginning in 1850, Carnegie worked as a messenger in the city's telegraph office. Ambitious and energetic, Carnegie soon became secretary to Thomas Scott, superintendent of the Pennsylvania Railroad, who was just beginning his highly successful career with the company. Carnegie worked his way up, succeeding Scott as superintendent of the Pittsburgh Division, and when Scott was hired to supervise military transportation for the Union upon the outbreak of the Civil War, he hired Carnegie as his assistant.

His wartime work brought home to him the increasing centrality of the iron industry to the American economy, and in one of the gambles that characterized his business life, Carnegie left the railroad and moved to the Keystone Bridge Company, an operation that replaced wooden bridges with stronger and more durable iron ones. With a foresight that was to characterize his future success, he recognized early on both the developing importance of steel and the tremendous value of the newly developed Bessemer refining system by which iron could be turned into steel. Working off this realization, Carnegie jumped into the developing steel industry, building a new steel plant in the Pittsburgh area, and in no time at all he had become the dominant figure in the industry. He capped his efforts with the founding in 1892 of the Carnegie Steel Company, an enterprise that merged the various individual assets he had accumulated over the years into one vertically integrated corporation. This pioneering approach allowed Carnegie to control each step of the steelmaking process from the mining of the ore to the

production and sale of the finished product. This vertical integration represented a singular advance in both control and efficiency and was an important business innovation.

The company grew, and Carnegie became a theoretical spokesman for an enlightened capitalism, preaching about the rights of workers and the value of unions as a vehicle to protect their jobs. However, his rhetoric did not match up with his reality in 1892, when Carnegie backed his manager, Henry Clay Frick, who had locked out the workers in the bloody Homestead Strike, an event that would forever leave a scar on Carnegie's reputation. Carnegie and Frick spent a lifetime breaking unions and preventing workers from organizing. At the same time, neither the strike nor an economic downturn later in the decade did anything to stop the growth of Carnegie Steel. By 1900, it was producing more steel than was the whole of Great Britain. However, he was tiring of the pressures of business, and when financier J. P. Morgan came to see him about a possible sale and merger that would result in the creation of a huge steel conglomerate, Carnegie was ready to deal, selling his company for \$480 million, a deal that created the world's first billion-dollar corporation—U.S. Steel—and made Carnegie the richest individual in the world.

In the aftermath of the creation of U.S. Steel, Carnegie undertook a second career as a philanthropist. Having often said that “the man who dies rich, dies disgraced,” he was determined to give away most of his fortune. From building hundreds of libraries across the country to supporting numerous colleges and universities, he was an untiring advocate of reading and learning. Critics point out that library building created no meaningful change in the lives of workers who lived in poverty for generations so that Carnegie could become one of the richest men in the world.

Carnegie opposed what he believed was the United States' first foray into imperialism when it acquired the Philippines and Cuba after the Spanish-American War, and in 1910, he formed the Carnegie Endowment for International Peace. One of the earliest proponents of a “league of nations,” he also built a “palace of peace” that would ultimately evolve into the World Court.

In 1886, Carnegie married Louise Whitfield, with whom he had a daughter, Margaret. He died at his summer residence in Lenox, Massachusetts, on August 11, 1919, of bronchial pneumonia. He was cremated, and his remains are interred at the Sleepy Hollow Cemetery in North Tarrytown, New York.

Carnegie Steel Mill

Andrew Carnegie built his first steel mill during the economic downturn known as the Panic of 1873, saving tens of thousands of dollars. Carnegie was a pure capitalist, becoming one of America's wealthiest industrialists through his genius in investing and building industry. He was a pioneer in industrial organization, motivation, and the application of new technology. He proved out the concept of supply chain management through vertical integration.

Carnegie immigrated to America from Scotland as a young boy after the automated loom had destroyed his father's craft as a weaver. Young Andrew started in a Pittsburgh cotton mill, but he rapidly adopted the new technology of the telegraph. He invested in the Pennsylvania Railroad, where he was employed. In 1862, Carnegie then purchased a \$40,000 share in an oil venture known as Columbia Oil, which would return over 400 percent by the end of the decade. Carnegie then searched for a new investment and went to England to study the emerging technology of Bessemer steelmaking. Steel was a new material and stronger than the wrought iron that was used to produce rails for the booming railroad industry. Carnegie saw a huge steel market if the cost of production could be brought down.

Carnegie planned to enter the new steel rail business by being a low-cost and high-technology

producer. First, Carnegie partnered with iron manufacturers and railroad executives to penetrate potential railroad markets. This allowed him to attack the wrought-iron rail market with a steel rail product. In 1875, Carnegie opened the world's largest steel mill and factory to produce steel rails for the railroad. Edgar Thomson Works at Braddock, Pennsylvania (near Pittsburgh), was named after Edgar Thomson of the Pennsylvania Railroad. Carnegie hired the best Bessemer steel engineer in the business, Alexander Holly, to build his new mill. Carnegie had competition in the steel business, but he focused on cost as his competitive advantage.

Carnegie continued to build during the Panic of 1873, saving significantly on construction costs. He hired some of the best and most experienced managers to build his management organization. He brought in railroad men as partners to boost sales. Carnegie and his partners endured the Panic of 1873 to see the mill roll its first rail on September 1, 1875. Carnegie was the first in the industry to apply cost accounting, breaking out the product cost for each process step. Carnegie used this to benchmark and to improve as well as to evaluate new process technology. Carnegie hired young managers by offering them stock and ownership in the company as motivation, based on their performance. These managers, tested in the fire of competition, became the best on the American scene. Over 30 of these young managers would become multimillionaires when Carnegie sold the business. Carnegie boys would go on to control over 40 percent of America's industrial assets.

Carnegie continued to expand and improve the mill, fully integrating the production of steel rails by 1883, using hot blast furnace pig iron produced at the mill rather than buying cold pig iron on the open market. Carnegie built some of the world's largest blast furnaces to drive the process cost down further. Realizing the advantage of vertical integration, Carnegie invested in coke production, using the coal-based fuel for his blast furnaces. Carnegie controlled the partnership and poured his profits into expansion of steel manufacturing versus the diversification that many suggested to him. His managers invented a new type of holding furnaces to allow liquid blast furnace iron to move to the Bessemer converter, further saving on

the cost of reheating. Carnegie instituted a policy of rapid technology implementation to reduce costs throughout the process.

With each improvement in process cost, Carnegie lowered the rail price to take more market share and gain economy of scale. Managers were rewarded with large percentages of cost savings to further motivate process cost reduction. Carnegie further rearranged the rolling operations to eliminate the need for intermediate heating between rolling. His cost push led him to start his own railroad to reduce plant transportation costs. Carnegie expanded the railroad to take iron ore from the Cleveland docks to his Braddock mill. Another part of his vertical integration was the buying of coalfields and coke ovens to produce his own fuel completely. By the 1890s, big railroads such as the Pennsylvania Railroad became the biggest customer of and supplier of services to the steel business. Vertical integration became one of the most successful business models of the Gilded Age. H. J. Heinz applied it in the food business, A. Busch in the beer industry, Henry Ford in auto production, and George Westinghouse in electrical appliances.

Carnegie was one of the first to talk of competitive advantage. He never let his mills lose their technological edge. At his Braddock mill, he perfected the new, clean steel production of open-hearth steelmaking. When he purchased a fairly new Bessemer steel plant at Homestead, Pennsylvania, he gutted it to convert it to the open-hearth process for tougher steel markets. He was the first American manufacturer to apply natural gas as an industrial fuel and the first to electrify his operations. He always maintained a technological edge over the competition, regardless of cost. By the end of the 1890s, Carnegie controlled the rail, structural steel, and armor plate markets.

Besides cost control, technology, and vertical integration, Carnegie mastered competitive advantage by market control. He was a feared competitor. He often targeted competitors, defeating them in the marketplace and taking them over. Carnegie benefited much from the McKinley tariffs, but to his credit, he reinvested in plant equipment and expansion. His one weakness was his poor labor relations. Eventually, Carnegie was bought out voluntarily by J. P. Morgan,

who formed the world's first billion-dollar corporation, U.S. Steel, in 1901.

Primary Document: Correspondence of Andrew Carnegie and Henry Clay Frick Regarding the Homestead Strike (1892)

While newspapers in the United States and Europe roundly criticized both Andrew Carnegie and Henry Clay Frick, who was chairman of the Carnegie Steel company, for their brutal treatment of strikers at their Homestead Steel plant in 1892, the two men saw breaking the workers, along with their demands for improved wages and working conditions, as a positive good. During and after the strike, Carnegie pretended to be saddened by the whole thing, but, as the letter and telegram exchange here show, Carnegie lied.

May 4, 1892: Letter to Frick

"One thing we are all sure of: No contest will be entered in that will fail. It will be harder this time at Homestead . . . On the other hand, your reputation will shorten it, so that I really do not believe it will be much of a struggle. We all approve of anything you do, not stopping short of approval of a contest. We are with you to the end."

June 10, 1892: Telegram to Frick

"Of course, you will be asked to confer, and I know you will decline all conferences, as you have taken your stand and have nothing more to say . . . Of course you will win, and win easier than you suppose, owing to the present condition of the market."

July 7, 1892: Telegram to Frick

"Cable received. All anxiety gone since you stand firm. Never employ one of these rioters. Let grass grow over works. Must not fail now. You will win easily next trial."

July 17, 1892: Carnegie Letter to Cousin

"Matters at home bad—such a fiasco trying to send guards by Boat and then leaving space between River & fences for the men to get opposite landing and fire. Still we must keep quiet & do all we can to support Frick & those at Seat of War. I have been besieged by interviewing Cables from N York but have not said a word. Silence is best. We shall win, of course, but may have to shut down for months."

November 18, 1892: Telegram from Frick at End of Lockout

"Victory!"

November 21, 1892: Telegram from Frick

"Strike officially declared off yesterday. Our victory is now complete and most gratifying. Do not think we will ever have any serious labor trouble again . . . Let the Amalgamated still exist and hold full sway at other people's mills. That is no concern of ours."

Late November 1892: Telegram to Frick from Italy

"Life is worth living again—Cables received—first happy morning since July—surprising how pretty Italia—congratulate all around—improve works—go ahead—clear track—tariff not in it—shake."

Carpet Sweeper

Carpet sweepers are mechanical devices for cleaning carpets. They were popular before the invention of the vacuum cleaner and are still being used today. Melville Reuben Bissell invented the carpet sweeper in 1876.

Bissell conceived of the idea for a carpet sweeper while working in his crockery and glassware shop in Michigan. Glassware and crockery were packed in sawdust, and Bissell wanted something to clean up the messy material. He invented a small box with rolling brushes inside; a handle, like a broom or mop handle, made the device easy to operate. Eventually, friends and customers wondered how they could also own such a cleaning device, and from there, a new business was born. Demand for carpet sweepers was pushed by the increasing affordability of home carpets and the difficulty in keeping them clean.

Bissell started selling carpet sweepers in 1883. When he died in 1889, his wife Anna stepped in to lead the business, becoming the first female CEO in America. She defended and protected the company's patents and marketed sweepers successfully throughout North America and Europe. A decade after taking control of the company, Anna Bissell had transformed her husband's small enterprise into the largest of its type in the world.

Sweepers became popular in the United Kingdom after the first Ewbank (Entwisle and Kenyon Ltd., now Earlex Ltd.) model went on sale in 1889. The Ewbank Carpet sweeper sold extremely well because it was both affordable and efficient. Queen Victoria loved the device so much, she insisted her palace be "Bisselled" every week.

A carpet sweeper is usually composed of a small box whose base is lined with rollers and brushes connected by a belt or gears. The sweeping mechanism works by rolling the base forward, thus using the belt and gears to rotate the brushes. This action allows for detritus to be collected into the removable container. Carpet sweepers frequently have a height adjustment function enabling them to work on different depths of carpet. The remains of the grit and grime can be dumped after use.

Bissell Inc. continues in operation as a private corporation, specializing in vacuum cleaners and related products, including carpet sweepers. New iterations were designed at the turn of the 20th century with rechargeable batteries and electric motor(s) to rotate the rollers and brushes. These new motorized cleaners are more efficient but more tedious because of weight and cords.

The history of carpet sweepers lives on with the floor-cleaning robots that have limited suction power and rely on sweeping to collect larger amounts of debris from the floor. While some newer, more expensive models of robotic vacuums rely only on vacuum motors, some models on the market, such as the Roomba (an autonomous robotic vacuum cleaner) combine suction and sweeping technologies.

Carver, George Washington (1861–1943)

George Washington Carver is credited with the development of innovative crop rotation methods. To make crop rotation viable, Carver advocated the use of "appropriate technology," an approach that sought to exploit naturally available resources (instead of expensive purchased products). Although Carver worked with many legumes, he achieved fame as the "peanut man" due to the press he received after he testified before the U.S. Congress. By the 1920s, Carver was world famous, had many influential acquaintances, and received many honors as a consequence of his innovations in agriculture.

Carver was born at some time during the American Civil War (1861–1865) on a slave plantation to slave parents in Diamond, Missouri. His mother, Mary, died when he was very young. Although the reason

has remained a mystery, Carver's father was absent. Consequently, Moses and Susan Carver, his owners (guardians after the war), raised him until he was a teenager. Carver was a sickly child, and the Carvers excused him from doing heavy agricultural work. He devoted much of his time to studying and caring for plants. Before long, he developed a reputation as the neighborhood's "plant doctor," even though he could neither read nor write. He left home in 1875 and wandered around in Missouri, Kansas, and Iowa in search of an education. During that time, he supported himself by doing laundry, cooking, and homesteading. After attending classes in a one-room schoolhouse and a high school in Kansas, he enrolled at Simpson College in Indianola, Iowa, in 1890. After a few years, he transferred to Iowa Agricultural College (later Iowa State College), where he earned both a bachelor's (1894) and a master's degree (1896) in agriculture. After graduation, Booker T. Washington (1856–1915), founder of Tuskegee Normal and Industrial Institute for Negroes (later Tuskegee University) in Tuskegee, Alabama, offered Carver a teaching position. Carver accepted Washington's offer. Although Carver had planned to stay at Tuskegee for just a few years and then return to school to pursue a doctorate, he stayed at Tuskegee for the rest of his life. Carver spent most of his career serving in the Tuskegee Agricultural Department in various teaching and administrative capacities.

The primary focus of much of his research had to do with helping farmers in the South make a better living. Due to the high market value of cotton, many farmers were growing it almost exclusively. Since they did not grow enough food crops to survive on, they had become dependent on cotton sale profits and loans. Unfortunately, the planting of cotton in the same fields year after year had depleted the soil of vital minerals and nutrients. Consequently, cotton yields diminished over time, leaving farmers unable to make a profit and deeper in debt. Carver's research showed that nitrate-producing crops such as peanuts and black-eyed peas could return the soil to acceptable growing levels. He assured farmers that they could increase agricultural productivity without the need to purchase

expensive fertilizers if they employed yearly crop rotations with either of these crops. However, if Carver's plan was to work, farmers needed to grow crops that they could both consume and sell. For this reason, Carver developed hundreds of uses for various crops, including peanuts and sweet potatoes.

In a portable school wagon, Carver and his students visited farmers and passed out bulletins that contained ways of transforming crops into numerous edible and marketable cash crops. He showed them how to transform peanuts into more than 100 products, including vegetable oil, cheese, facial cream, ink, soap, wood stain, and butter. Although it took some time, peanut butter became popular by the 1920s. He showed farmers hundreds of uses for sweet potatoes, including transforming them into cereal, coffee, shoe polish, paste, oils, flour, sugar, and bread. In addition, he developed about 60 uses for the pecan. Instead of spending money on food, Carver suggested the consumption of wide weeds, which he called "nature's vegetables." Carver believed that Americans should never go hungry due to nature's inclination to provide the earth with weeds. His bulletins contained many recipes for transforming "wild crops" (including wild onions, wild grass, and wild lettuce) into meals. Without a doubt, these wild creations were an acquired taste, and not very many people opted to consume them unless absolutely necessary. In fact, a few businessmen attempted to capitalize on Carver's recipes, but their businesses went bankrupt. Carver also insisted that farmers could raise more pigs for less money by feeding them acorns that grew wild in the forest instead of expensive cornmeal. Carver also developed many hybrid plants. For example, he developed a hybrid cotton plant to combat the boll weevil. Since the hybrid matured earlier than regular cotton, it could be harvested before the boll weevil had a chance to infest it. He extracted a wide range of dyes from the Alabama clay soil. The dyes were then used to create wood stains and paints.

In 1920, Carver spoke at a convention sponsored by the United Peanut Association of America. Members of the association were impressed with Carver's

speech, and they sponsored an all-expenses-paid trip for him to testify before Congress about the many uses of American peanuts and to ask for a protective tariff. Carver's speech got off to a rough start, as some white politicians were not keen on listening to an African American man. However, Carver's warm disposition and informative presentation won them over. Carver's visit to Congress resulted in a lot of press and gained him worldwide fame. Inventor Thomas Alva Edison (1847–1931) offered Carver a job in his invention factory and offered to pay him a yearly salary that would have exceeded what the U.S. president earned. Carver declined the offer, because he did not want big business ideals to hamper his ability to freely benefit all of humanity. For this same reason, he patented only a few of his hundreds of innovations. Carver received an honorary doctorate, and he was made a member of the British Royal Society of Arts. World leaders, including President Franklin D. Roosevelt (1882–1945), Soviet leader Joseph Stalin (1878–1953), and Indian leader Mohandas Gandhi (1869–1948) sought his advice. He received the Theodore Roosevelt Medal for his distinguished achievements in science.

Carver's accomplishments and fame gave him the opportunity to go on a speaking tour of several all-white colleges. In 1923, the National Association for the Advancement of Colored People (NAACP) awarded him the Spingarn Medal for making a great contribution to the advancement of his race. Carver preferred to devote his time to science rather than politics. During a time of racial segregation, he never took any particular stand against the social order. Unfortunately, all sorts of groups claimed Carver as their role model, and they embellished certain aspects of Carver's life to fit their views. Consequently, the line between truth and myth became blurred regarding some aspects of Carver's life story.

Carver had a gift for making friends. He became a trusted advisor to many of his students. Carver corresponded with cereal manufacturer John Harvey Kellogg for several years. Both men had an interest in the health benefits of certain foods. Carver also struck up friendships with tire manufacturer Harvey

Firestone (1868–1938) and automobile manufacturer Henry Ford (1863–1947). Occasionally, Carver would visit Ford's laboratory in Dearborn, Michigan, and Ford would visit Carver at Tuskegee.

During the last few years of his life, Carver became feeble due to an extended illness. After hearing about his friend's state, Ford sent money so that an elevator could be built in Carver's dormitory. Carver had a well-established reputation for frugality in his personal affairs, which corresponded with his views on wisely using Earth's resources. Even during his fame-making appearance before Congress in 1921, he wore an old, tattered suit. When his acquaintances tried to convince him to buy a new suit for the occasion, he rebuffed them by explaining that Congress was more interested in what he had to say than in how he looked. He told an interviewer in 1917, "Well, someday I will have to leave this world. And when that day comes, I want to feel that my life has been of some service to my fellow man" (Leavitt, 23). He saved most of his meager salary. He never married, and he had no children. When he died on January 5, 1943, he left his life savings of \$33,000 and his estate (worth \$27,000) for the establishment of a research institute for agriculture at Tuskegee. He was buried on the Tuskegee campus beside Booker T. Washington. Ten years after his death, Carver's birthplace was made into a national monument.

Primary Document: George Washington Carver Addresses Congress (1921)

In 1921, George Washington Carver appeared before U.S. Congress on behalf of the United Peanut Association of America, an organization founded at the Tuskegee Institute where Carver worked, to promote peanut-based agriculture in the United States. He proposed a tariff on peanuts from other countries to protect American peanut growers. Carver took a number of products with him to his hearing, which he describes in his testimony.

Mr. Carver: Mr. Chairman, I have been asked by the United Peanut Growers' Association to tell you something about the possibility of the peanut and its possible extension. I come from Tuskegee, Ala. I am engaged in agricultural research work, and I have given some attention to the peanut, but not as much as I expect to give . . . I am especially interested in southern crops and their possibilities, and the peanut comes in, I think, for one of the most remarkable crops that we do not already know, and you will also observe that it has possibilities that we are just beginning to find out. If I may have a little space here to put these things down, I should like to exhibit them to you. I am going to just touch a few high places here and there because in 10 minutes you will tell me to stop. This is the crushed cake, which has a great many possibilities. I simply call attention to that. The crushed cake may be used in all sorts of combinations—for flours and meals and breakfast foods and a great many things that I have not time to touch upon right now.

Then we have the hulls, which are ground and made into meal for burnishing tin plate. It has a very important value in that direction, and more of it is going to be used as the tin-plate manufacturers understand its value. Now there is another confection. It is peanuts covered with chocolate. As I passed through Greensboro, S.C., I noticed one of the stores that this was displayed on the market, and, as it understood better, more of it is going to be made up into this form.

B. Carver: Here is a breakfast food. I am very sorry that you can not taste this, so I will taste it for you. [Laughter.]

Now, this is a combination and, by the way, one of the finest breakfast foods that you or anyone else has

ever seen. It is a combination of the sweet potato and the peanut, and if you will pardon a little digression here I will state that the peanut and the sweet potato are twin brothers and can not and should not be separated. They are two of the greatest products that God has ever given us. The can be made into a perfectly balanced ration. If all of the other foodstuffs were destroyed—that is vegetable foodstuffs were destroyed—a perfectly balanced ration with all of the nutriment in it could be made with the sweet potato and the peanut. From the sweet potato we get starches and carbohydrates, and from the peanut we get all the muscle-building properties . . . Here is another breakfast food that has its value. I will not attempt to tell you, because there are several of these breakfast foods that I will not take the time to describe, because I suppose my 10 minutes' time is about up. Of course I had to lose some time in getting these samples out.

Congressman Garner: I think this is very interesting. I think his time should be extended.

Congressman Rainey: The varied use of the peanut is increasing rapidly?

Mr. Carver: Yes, sir. Congressman Rainey: It is an exceedingly valuable product, is it not?

Mr. Carver: We are just beginning to learn the value of the peanut.

Congressman Rainey: Is it not going to be such a valuable product that the more we have of them here the better we are off?

Mr. Carver: Well, that depends. It depends upon the problems that these gentlemen have brought before you.

Mr. Rainey: Could we get too much of them, they being so valuable for stock foods and everything else?

Mr. Carver: Well, of course, we would have to have protection for them. [Laughter.] That is, we could not allow other countries to come in and take our rights away from us. I wish to say here in all sincerity that America produces better peanuts than any other part of the world, as far as I have been able to test them out.

Mr. Rainey: Then we need not fear these inferior peanuts from abroad at all? They would not compete with our better peanuts?

Mr. Carver: Well, you know that is just about like everything else. You know that some people like (margarine) just as well as butter, and some people like lard just as well as butter. So sometimes you have to protect a good thing . . . That is all a tariff means—to put the other fellow out of business. [Laughter.]

Cash Register

James Ritty invented the cash register in 1879 with the help of his brother John. Ritty had struggled with corrupt bartenders before developing a machine that could track the sales of a store. He came up with several variations of the concept, the first of which had a clock-like face and two rows of keys (similar to a typewriter) that tracked the sales. Ritty patented the machine after its second iteration.

A modern aspect of the cash register was added to the third design, which used tabs to display monetary values to both the customer and the clerk. James and John Ritty called it “Ritty’s Incorruptible Cashier.” Sales became public with the fourth iteration, which used paper to track the sales of the day, making a hole at each sales mark. This allowed businesses to count the sales at the end of the day. These early iterations of the cash register pioneered the way for John Patterson, who bought the patent in 1884 and turned the cash register into a worldwide phenomenon, further improving its durability and efficiency. In recent years, cash registers have come to involve newer technologies, including iPads, to account for alternate forms of payment, including credit and debit cards and online payments.

Celluloid

Commonly known for its use in photography and films during the early days of both industries, celluloid, a form of fabricated plastic, was invented by John Wesley Hyatt in 1870. It consists of a thin, transparent plastic that was also flammable; acetate safety film replaced it in the early 1950s, but the name “celluloid” stuck and is still used in phrases such as “Celluloid Heroes,” a song popularized by the Kinks. Despite its permanent connection with the movies, celluloid plastic was also used for a variety of inexpensive items such as knife handles, holiday decorations, razors, and hair ornaments.

Hyatt created celluloid by mixing a main base of cellulose with variously colored pigments, fillers, camphor, and alcohol. The inventor and industrialist was previously known for the creation of the first artificial plastic. Hyatt worked on a replacement for ivory billiard balls; however, none of his experiments were successful. He eventually found a plastic material that could be made by mixing nitrocellulose with alcohol and camphor. Nitrocellulose is composed of a flammable nitrate of cellulose from wood or cotton. Hyatt paired up with his brother Isaiah Hyatt and patented their pale yellow film with brown ridges on the edge as “celluloid.”

The brothers established the Celluloid Manufacturing Company and moved from Albany, New York, to Newark, New Jersey, where John Hyatt came up with

many other inventions—such as roller bearings, sugarcane mills, and sewing machines. In the 1870s, photographer John Carbutt contracted with the company to make celluloid strips coated with photosensitive gelatin. Early experiments by Thomas Edison in motion pictures used this version of celluloid. In 1889, Eastman Kodak applied for patents on a flexible photographic celluloid that gave birth to the motion picture industry.

Celluloid is rarely used in the 21st century, both because of the digital revolution and because other, more durable and less flammable products have replaced it. Only two celluloid factories, both in China, remain in the world.

Coca-Cola

Coca-Cola is an American soft drink introduced to the public in 1886. In its infancy, it was promoted as a beverage with medicinal properties. As America's favorite soft drink for a good portion of the 20th century, Coca-Cola has expanded its reach throughout the world. In 2012, it was designated as the most valuable global brand.

In 1886, John “Doc” Pemberton invented the beverage in Atlanta, Georgia, after experimenting with various combinations of ingredients to make a drink that was tasty and had medicinal value. Pemberton was a pharmacist who believed in the use of natural ingredients such as herbs, plants, and vegetables to help heal illnesses and diseases. Although skilled in conjuring up concoctions, Pemberton was a poor businessman. He never repaid loans and was always on the lookout for new capital and potential partners. He found three men who were willing to put up money and join in partnership. In January 1886, he formed a

This magazine advertisement for Coca-Cola, ca. 1890, shows the popularity of the product invented in 1866 by John Pemberton, an American pharmacist. (Library of Congress)

company with Ed Holland, Frank Robinson, and David Doe, and the Pemberton Chemical Company was incorporated. The goal was to create the perfect drink that they could sell at an affordable price.

Thinking that Atlanta natives would want something to drink during the scorching hot summers besides tea and coffee, Pemberton first determined to develop a sweet and syrupy beverage with caffeine extracted from African kola nuts. However, he discovered that the caffeine from the liquid extraction was extremely bitter and not drinkable. Through trial and error, he found that if he put in a drop of the liquid extraction and added synthetic caffeine instead, the taste was palatable. The man-made caffeine was still bitter although not as strong as the original liquid extraction. Then, Pemberton sought to disguise the bitterness of both types of caffeine by making the beverage exceedingly sweet.

Other Coca-Cola ingredients included sugar, caramel (or burnt sugar, which gave the drink its dark amber color), lime juice, citric acid, and phosphoric acid. For flavoring, he included vanilla extract, elixir of orange, and oils from fruit, herbs, and trees such as lemon, nutmeg, spicebush, coriander, and neroli (a fragrant, pale yellow essential oil from orange blossoms), and cassia (a dried, rough bark from trees found in Asian tropical regions). Last, Pemberton added last cocaine to the drink, which had been extracted from the coca leaf in liquefied form. At the time, cocaine was viewed as a wonder drug, and Pemberton thought that when he combined it with the caffeine, his resulting drink would make people feel happy, alert, and well. The final mixture was a thick syrup that could be sold to soda fountains; Coca-Cola drinks were made by combining the syrup with carbonated water.

One of the partners, Robinson, chose the name Coca-Cola. In June 1887, Pemberton received a patent. For testing, he had samples brought to Willis Venable Soda Fountain located three blocks away in Jacob's Pharmacy. For marketing, Robinson worked on fine-tuning the logo design with an engraver. He had coupons printed with an offer of two free samples per person that were mailed out to a portion of Atlanta's population. Posters, streetcar signs, and oilcloth banners for soda fountains were also created. A salesman was hired as well to travel to other cities in the South. Sales picked up modestly with these efforts.

Not long after, Pemberton became sick. He sold the company to Venable, who didn't have any money. Pemberton's friend George Lowndes agreed to put some up, and the contract they signed stipulated that Venable would be Lowndes's partner and each man would own a third of the rights to the product. When Robinson, one of Pemberton's original partners, discovered the deal, he tried to sue Pemberton, but to no avail. Pemberton was penniless and died shortly after giving up control of his company.

Robinson's luck changed when he encountered Asa Candler, a successful pharmacist and drugstore owner who had hired Robinson as a part-time bookkeeper. In 1888, Robinson saw an opportunity to buy back Coca-Cola when Venable violated the contract, and Lowndes decided to sell his two-thirds of the shares. Robinson convinced Candler to buy the

company. He acquired full ownership of Coca-Cola and put Robinson in charge. In 1891, Candler decided to get out of the pharmacy business to devote himself full time to Coca-Cola. The men decided to refine the formula, in part because the Coca-Cola syrup turned rancid when the phosphoric acid in it interacted with the tin of metal cans. Glycerin was then used as a preservative and proved to be a stabilizing agent.

At the same time, the company altered the amounts of both coca leaf and kola nut extractions in response to a national debate about the negative effects of cocaine and caffeine. The company began bottling Coca-Cola in 1891 and in 1915 introduced the iconic "hobble-skirt bottle" design. Robert W. Woodruff assumed the presidency of Coca-Cola in 1923, and he expanded the soft drink's appeal to Europe, Asia, and parts of Africa. Under his leadership, Coca-Cola continued to thrive and became the product that was recognized worldwide. The company first canned its beverage in 1955.

Through his leadership, Coca-Cola has maintained its dominance in the beverage industry for almost a century, with the notable exception of the "New Coke" imbroglio of 1985. That's when the company changed the formula, tested it, and found that consumers preferred the new version. Yet, when the company introduced New Coke to consumers, the public reacted negatively, creating a firestorm of controversy. Coca-Cola returned to its old formula within three months of New Coke's debut.

As carbonated drink competition rose and demand for high-calorie drinks fell in the late 20th and early 21st centuries, Coke lost its market dominance. But there can be little doubt that Coca-Cola continues to be a major part of the global economic marketplace.

Cotton Candy Machine

The cotton candy machine was invented in 1897 by William J. Morrison and John C. Wharton. Machine-spun sugar gained wide popularity when it was served at the 1904 World's Fair in Missouri as "fairy floss."

Although the electric cotton candy machine dates to the turn of the 20th century, cotton candy's roots can be traced to centuries earlier. Previously, spun sugar had been a treat reserved for the wealthy aristocracy and was largely used as decoration for desserts and not as a singular confection. Records from as early as the 15th century as well as everyday cookbooks from the 18th century include recipes for the sweet; however, the process was complex as well as time- and labor-intensive.

Morrison (1860–1926), the better known of the two inventors, was both a dentist in Nashville, Tennessee, and a children's book author, and he held a multitude of other patents, including for a process for extracting oil from cottonseed, as well as being credited for the first water purification plant in his hometown. He attended the University of Tennessee Dental College and became president of the Tennessee State Dental Association. However, his most widely known contribution is as the coinventor of the electric cotton candy machine. Along with the confectioner John Wharton, also of Nashville, they invented and patented a candy machine (patent number US618428 A, filed on December 23, 1897) that worked very much like modern ones. Even though many sources attribute the electric cotton candy machine to Morrison and Wharton, their original patent did not specify that the design could operate solely or predominantly on electric power; rather, the machine utilized "foot-power," although they specified that any source of power could be used without changing the overall mechanics of the invention.

The machine itself consisted of a metal bowl that contained a central spinning head perforated with very small holes. The machine melted sugar, and forced air would push it through the perforations. Cotton candy, or "fairy floss," as it was then known, is the equivalent of sugar glass. The sugar syrup instantly crystallizes into long, thin strands, creating a delicate confection that is mostly air. The cotton candy machine allowed Morrison and Wharton to produce a treat similar to spun sugar but much more ephemeral, silk-like, and

delicate as well as to do so more cheaply and quickly. The cotton candy machine also resulted in the now well-known cloud texture, while the earlier spun sugar's strands were unformed and more distinct.

Morrison and Wharton introduced their cotton candy-making invention to the public at the St. Louis World's Fair of 1904. Their "fairy floss" is reported to have delighted fairgoers, with nearly 70,000 helpings sold during the fair's six-month duration. In fact, the cotton candy machine was such a hit that it took home the prize for "Novelty of Invention." In the 1920s, another dentist, Josef Lascaux, attempted to improve Morrison and Wharton's design, but his invention was not nearly as popular, successful, or arguably improved. However, it was Lascaux who coined the term "cotton candy," and that is the name that has been used in the United States ever since, although the treat is still known as "fairy floss" or "candy floss" in other countries.

Cotton candy remains a staple at state and county fairs and carnivals, and many companies package and sell it commercially. There are even machines for making cotton candy in one's home. Both flavorings and colorings can be added to produce a multitude of colors and flavors, but cotton candy is produced in exactly the same way as it was originally. Numerous patents have been filed for improvements on Morrison and Wharton's original mechanism, generally by candy-making companies, to make cotton candy easier to mass-produce commercially.

Crayons

The Crayola crayon, an iconic staple of American youth, first appeared in 1903 thanks to the inventive minds of Edwin Binney and C. Harold Smith. The crayon is a colored wax stick used for drawing and other art. Though Crayola crayons are the most famous

and iconic crayons, many companies make crayons out of wax, charcoal, and chalk.

Cousins Edwin and Harold first began working together as salesmen in 1880 under Edwin's father, Joseph Binney, at his company, Peekskill Chemical Works, in Peekskill, New York. After Edwin's father retired in 1885, Edwin and Harold formed a new partnership and renamed the company Binney & Smith. Having grown up together, the partners developed and maintained a strong working and personal relationship, a true asset to the success of their company. They even alternated being its president and vice president. Smith's outgoing personality served him as the lead salesman. Binney's quiet and thoughtful demeanor made him a successful businessman. Binney & Smith emphasized listening and responding to consumer needs, a habit and value that in turn sparked their notable contribution to American society.

Before making their defining invention, Binney and Smith produced red oxides, used in paint, and carbon black. After numerous requests from schoolteachers, the duo created the first dustless school chalk called "An-Du-Septic Dustless Blackboard Chalk" in 1902. With schools becoming Binney & Smith's largest client, the team shifted focus to create a safe, clean, non-toxic and affordable crayon to market to classrooms. In 1903, the eight-pack of Crayola crayons appeared, featuring red, orange, yellow, green, blue, violet, brown, and black, priced at a nickel a carton. Credit for the name "Crayola" goes to Edwin's wife, Alice, who combined the French word "*craie*," meaning "chalk," with "-ola" from "oleaginous," meaning "oily." Initially, schools could not afford the Crayola product, so the U.S. government became the first patron of the boxed crayons, distributing them to Indian reservations.

Despite the passing of the innovative duo, Smith in 1931 and Binney in 1934, the Crayola company continued its success. Expanding upon the relationship between Crayola and the school systems, the company created a teacher-training workshop in 1948 to demonstrate the many ways in which teachers could utilize Crayola products in their classrooms. Shortly after the launch of that orientation program, Crayola released the 48-crayon box displaying the notable "stadium seating" design. Ten years later, the even more notable 64-crayon box with a built-in sharpener

appeared in stores. While the success of the Crayola crayon and other Crayola products continued to evolve over the decades, in 1984, Binney & Smith became a subsidiary of Hallmark, who still has ownership today. Just shy of a decade after Hallmark purchased the company, Crayola celebrated its 90th birthday by introducing 16 new colors to the existing ones, selling them in a 96-count crayon box.

Creating the Crayola crayon requires a detailed process. Liquefied paraffin (wax) is pumped from storage tanks to vats and mixed with powdered pigment for color and talc for texture and to bind all the components together. The vats of material are heated to 240°F and then transferred to a 40-pound bucket. From the bucket, contents spill in controlled quantities onto a table of molds, where the mixture settles into its crayon-shaped divots and cools. After about seven minutes, a machine cuts away excess wax, and the crayons are pushed from the mold to a tray where workers inspect each crayon by hand, discarding any that are below quality standards. Approved crayons move down the assembly line to be wrapped with the Crayola label and then packaged.

Since the basic eight of 1903, more than 600 variations of Crayola crayons have been created. Over 3 billion crayons are produced annually at the Binney & Smith plant in Easton, Pennsylvania. The Crayola crayon tethers generations to nostalgic childhood memories while building the creative minds of future generations. In fact, a study conducted at Yale University ranks the smell of the Crayola crayon at 18 out of 20 of the most identifiable scents among American adults, solidifying the effect that this company and its product has on our society.

Curling Iron

A curling iron is a rod-shaped instrument that uses heat to curl hair. Curling irons are made of a variety of materials, including Teflon, metal, and titanium. The shape of the rod can be cylindrical, conical, or that of a reverse cone. Types of curling irons include Marcel; spring-loaded; and clipless, handled irons. The Marcel handle requires pressure to be applied to the clamp; however, the handle of the spring-loaded style does not require pressure. Hair is curled around the rod on a clipless handle version.

Historians are unsure who invented the first curling iron, as they date back to 2000 BC. American-born inventor Hiram Maxim obtained the first patent for one in 1866, improving the design. He also invented the Maxim Gun, a portable, fully automatic machine gun, and an amusement ride that he called “the Captive Flying Machine.” Maxim claimed to have invented the lightbulb, though Thomas Edison filed the first lightbulb patent in 1878.

The curling iron has evolved and been redesigned throughout the years. In 1959, Roger Lemoine and Rene Lelievre invented the electric curling iron that is widely used today.

Diner (Horse-Drawn)

Walter Scott (1841–1924) is credited with creating the first late-night eatery on the eastern coast of America with quick, walk-up service—the precursor to the all-night American diner and even today’s food trucks. The inception of this unique café experience began inauspiciously out of a wooden, two-wheeled

pushcart. Born out of a need for late-night, inexpensive, homemade hot meals, Scott’s lunch cart’s defining difference from restaurants of the period was mobility and service to an after-hours clientele. Over time, the evolution of the lunch cart to stationary diner was from pushcart to horse-drawn wagon to a manufactured structure built off-site and then delivered to and assembled at a permanent location.

Scott was born in Providence, Rhode Island, to Juliet Howland Scott and Joseph A. Scott on November 28, 1841. After the death of Scott’s father, the enterprising young man took to the streets as a pushcart vendor to financially aid his widowed mother. With the outbreak of the American Civil War, Scott tried unsuccessfully to enlist and then tried his hand at farming in New Jersey—but with no success. At that time, pushcarts sold raw foods such as fruits and vegetables but could not offer heated products or full entrées.

Returning to Rhode Island, Scott secured a job at the *Providence Evening Press* and the *Morning Star* newspapers. Working late into the night, Scott keenly felt the lack of available meals for him and his fellow newspapermen. Restaurants of the era closed after the supper hour, leaving a late-night community fending for themselves. Returning to his street vendor roots, Scott built a pushcart and began selling premade sandwiches and hot coffee out of his specially designed wooden cart. Street vendors were not unusual in that era, but mobile, after-hours meal service was. Innovative for its time, demand for it increased, and he left the newspaper business behind to pursue his mobile food venture full time.

By 1872, Scott’s enterprise had expanded to include a horse-drawn wagon. He redesigned a freight wagon, adding a roof, four walls, and a door. Inside, he created a kitchen workspace with countertops and storage. With Scott inside the wagon, he took orders, cashiered, and served through two open windows. With his newly designed food wagon, Scott guided its horse through the streets of Providence late at night, catering to neighborhoods where restaurants had closed for the evening, providing hot food for an all-night crowd of factory workers, newspapermen, and after-hour bar- and theatergoers.

With Scott’s innovation, customers lined up at his window, placed their orders, paid for them, and received their meals. Thirty cents would buy a plate of

chicken, and a nickel would buy a hot sandwich made from fresh-baked bread or a large slice of huckleberry, apple, or mince pie. As his business grew, Scott expanded his menu to include a variety of sandwiches made with egg, ham, or chicken; pies; beans; hot dogs; and hard-boiled eggs. By 1887, his hometown newspaper, the *Providence Journal*, reported Scott as “the Veteran Lunch man.”

Scott’s idea caught on throughout the region. With increased competition by other entrepreneurs came further innovations and variations. Competitors began offering an enclosed dining experience, complete with kitchen and seating for customers, all housed inside an enclosed, mobile wagon.

The manufacturing of commercial lunch wagons had begun, and by 1898, the United States Lunch Wagon Company operated wagons in 25 cities. By the time of Scott’s retirement in 1917, lunch wagons had so proliferated that city ordinances began regulating the now-aging food wagons, limiting their presence to the time from dusk until dawn. To circumvent city regulations, industrious lunch wagon owners found semi-permanent, off-street locations for their wagons and thus were able to operate around the clock. Referred to as “lunch cars,” “dining cars” or “night lunch wagons,” their popularity continued to grow, and by 1924, they became known as diners, evolving into the iconic American diner experience we know today.

Dishwashing Machine

Josephine Cochrane was the inventor of the first commercially successful dishwashing machine, which used water pressure instead of scrubbers to clean

dishes. She received a patent for the device on December 28, 1886. Her company, Cochrane’s Crescent Washing Machine Company, is now part of Whirlpool Corporation.

Cochrane was born in Shelbyville, Illinois, to John Garis, a civil engineer, and Irene Fitch Garis. Her maternal grandfather, John Fitch, was an inventor who was awarded a steamboat patent. She married William Cochran (Josephine added the “e” to their name) on October 13, 1858. He became a prosperous dry goods merchant and local politician. The pair threw many parties, and Cochrane soon became frustrated with the servants, who mishandled the family’s heirloom dishes. Realizing that washing the dishes herself was tedious, Cochrane dreamed of a machine that used water jets to do the job. William’s death, in 1833, left Cochrane heavily in debt, motivating her to turn her dream into a reality.

The first patent for a dishwashing machine was issued to Joel Houghton in 1850, for a wooden machine with a hand-turned wheel that splashed water on dishes. In the 1860s, L. A. Alexander added a geared mechanism that allowed a user to spin a rack of dishes through a tub of water. Neither of these devices was particularly effective or commercially viable. Cochrane built her prototype in a shed behind her home with help from George Butters, a local mechanic employed by the Illinois Central Railroad. She constructed wire compartments to hold plates, cups, and saucers. These compartments were placed inside a wheel that lay flat inside a larger copper boiler. A motor turned the wheel and pumped hot, soapy water over the dishes.

Cochrane received her first patent on the Garis-Cochran Dish-Washing Machine in 1886. She established the Cochrane’s Crescent Washing Machine Company, and her first customers were primarily restaurants and hotels. Housewives were less interested in the machine for a number of reasons; some women enjoyed washing dishes by hand and felt they did not need the machine. Cochrane’s dishwasher also required a great deal of hot water, and many homes did not have hot water heaters large enough to supply the machine.

In 1893, Cochrane convinced restaurants at the World’s Columbian Exposition in Chicago to use her

invention, and her dishwasher was exhibited in Machinery Hall, where it won a prize for design and durability. She soon had enough business to open her own factory in an abandoned schoolhouse, and her client list grew to include hospitals and colleges. Homemakers would eventually embrace the dishwasher but not until the mid-20th century. Cochrane was still personally selling her machines until shortly before her death in 1913. In 1916, Hobart bought Cochrane's and changed its name to that of the KitchenAid brand. Hobart and KitchenAid are now part of Whirlpool Corporation.

Dow Chemical Company

The Dow Chemical Company (Dow) sells more than 2,000 different products, including chemicals and plastics. Dow survived early challenges due to the founder's vision, perseverance, and innovation. Both world wars created opportunities for Dow to grow and expand its product line. In spite of controversies surrounding weapon sales, health issues, pollution, and tax evasion charges, Dow has continued to grow and produce innovative products.

Herbert Henry Dow (1866–1930) founded Canton Chemical, his first company, in 1890. While several companies exclusively extracted bromine (for salt) from brine in underground reservoirs, Dow was interested in extracting other chemicals as well. After Canton Chemical went bankrupt, he founded Dow in 1897. At a time when many people still viewed the electric lightbulb as a novelty, Dow's use of electric current to extract bromides from brine was innovative. Dow produced bleaching agents from bromides, which it sold to Kodak (a photography company founded in 1888).

In 1900, Dow grew due to a merger with Midland Chemical Company. The larger Dow then began to sell bromides in Europe. However, a group of European bromide producers banded together in a price war to try to push Dow out of business. The German-British cartel sold its product in the United States at \$.88 a pound (below cost). The only way that Dow could make a profit was by selling its product at no lower than \$1.65 a pound. Many U.S. bromide-producing companies closed during the price war. However, Dow helped his company survive during these difficult economic times by purchasing imported bromide in New York at cartel-set, below-cost prices and then selling it in Europe (where the price was still \$1.65 a pound).

Although Germany still dominated the world chemical market, during World War I (1914–1918), German chemical producers stopped selling their products to the United States. Consequently, Dow (and a handful of other U.S. chemical producers) supplied U.S. industry with needed products. The need for various wartime supplies also encouraged U.S. companies to expand their product lines. Dow began making phenol (for explosives) and magnesium (for incendiary devices). Later uses of Phenol included the manufacture of plastics, antiseptics, and disinfectants. One of the most important later applications of magnesium was in the manufacture of light alloys for the aerospace industry.

After the war, the U.S. Congress protected U.S. chemical makers by imposing tariffs. Dow's yearly sales climbed from \$4 million in 1920 to \$15 million by 1930. After Dow's death in 1930, his son Willard ran the company. In later years, Dow began extracting bromine from seawater (1933), entered the plastics business (1935), and expanded internationally with the establishment of Dow Chemical Canada, Ltd (1942). In 1943, Dow and Corning Glass merged to form the Dow Corning Company, which specialized in silicone products.

After World War II (1939–1945), Dow expanded its research and development to include more household-type products. In 1947, Dow became a corporation (a public company that trades its shares on a stock exchange). Willard died in a plane crash in 1949, and Lee Doan (his brother-in-law) took over operation of the company. That year, Dow's yearly sales were \$200

million. Under Doan's leadership, Dow's yearly sales quadrupled within a 10-year period. In 1952, Dow expanded outside of North America with the establishment of Ashai-Dow in Japan. The next year, Saran Wrap (a thin and clingy plastic for wrapping food) became a household product and transformed Dow into a high-profile company.

In 1964, Dow exceeded \$1 billion in annual sales, and in 1968, Ziploc bag technology (reusable and resealable zippered bags mostly used for food storage) was test-marketed and later sold to S. C. Johnson & Son. During the Vietnam conflict (1955–1975), Dow produced napalm (a highly sticky and flammable jelly used in bombs and flamethrowers) and Agent Orange (a chemical defoliant). By the mid-1960s, college students protested against Dow's involvement in the war. Some Dow representatives defended the company by arguing that Dow had no control over U.S. foreign policy. At the same time, other representatives argued that U.S. troops should have weapons that the Pentagon believed to be necessary. After the war, Dow executives sought to erase the stigma associated with civilian Vietnamese casualties and to reestablish a consumer-friendly image.

However, Dow was plagued by concerns over public health issues, environmental damages, and charges of tax fraud. In the 1980s, Dow faced public scrutiny with high-profile lawsuits filed by many women who claimed that the company's silicone breast implants caused autoimmune disease and cancer. Although Dow settlements with breast implant recipients totaled more than \$3 billion, over 20 independent studies found no causal relationship between silicone and these illnesses. In 1972, Dow introduced Lorsban, an insecticide, but it was banned by the Environmental Protection Agency (EPA) in 2000. After decades of study, the EPA had concluded that the widely used product could cause brain and nervous system damage to young children. In 2003, Dow reached an agreement with the EPA to clean up several contaminated waterways and paid millions of dollars for other pesticide-related damages. In 2013, a U.S. federal judge found Dow guilty of tax evasion. Although Dow appealed the ruling, a higher court rejected the appeal.

Between the late 1980s and the early 2000s, Dow merged with several other companies. In 2001, Dow surpassed DuPont as the largest chemical company in the United States. By this time, Dow had 50,000 employees and annual sales of \$27.8 billion. After some restructuring, DowDuPont (the world's largest chemical company) was created with the merger of Dow and DuPont in 2017. According to the company's business philosophy, the chemical industry "still has vast potential for technological advancement, as it works to identify and solve problems facing the world."

du Pont, Pierre (1870–1954)

Pierre S. du Pont was an American businessman whose work as chairman of both E. I. du Pont de Nemours and Company and General Motors played an important role in the industrial growth of the United States in the first decades of the 20th century.

Pierre S. du Pont was born on January 15, 1870, in Wilmington, Delaware. He was one of 11 children born to Lammot and Mary Belin du Pont. His father, who had moved the family business away from its focus on the production of gunpowder for ammunition and then contributed importantly to the early development of dynamite, died in an explosion, and the 14-year-old Pierre assumed so much of the responsibility for his younger siblings that some of his brothers called him "Dad."

Despite these challenges, du Pont attended William Penn Charter School in Philadelphia and then the Massachusetts Institute of Technology (MIT), from which he graduated in 1890 with a degree in chemistry. Returning to Delaware, he became a chemist in the family business, the DuPont Company, where he codeveloped the company's first commercially usable smokeless gunpowder. In 1899, he left the family business and assumed the presidency of the Johnson Company, a Lorain, Ohio operation that primarily produced rails for trolley and streetcar systems. Working with a cousin, Thomas Coleman, and discovering a skilled assistant in John J. Raskob, the company was a success, but after a short time, it was sold. Then, in 1902, with Coleman and another cousin, Alfred du Pont, Pierre bought and reorganized the family's operations to prevent their purchase by an outside firm. Raskob joined the newly created business as Pierre's assistant. Du Pont served the new company in a succession of roles, including treasurer, executive vice president, and acting president, before finally serving as president from 1915 until 1919. In those roles, he was central in transforming the DuPont Company into what many business historians consider the first modern corporation. His innovations in the technical, financial, and organizational areas were critical to the company's evolution from a family-run business to one that became noteworthy for its professionally managed corporate structure. Du Pont was a driving force behind the decision to divide power, separating the side of the organization that focused on the daily operations of the company from the other branch, which looked at long-range planning and operations.

By the time du Pont assumed the presidency of DuPont in 1915, Raskob, who would go on to head the national Democratic Party under New York governor Al Smith, had become his most trusted aide, and at his urging, du Pont began to purchase large amounts of stock in the newly created General Motors. With DuPont's profits having soared during World War I, the company diversified, adding paint, plastics, and dye to its product line. At the same time, in addition to his own investments, du Pont also had put a lot of the company's money into GM, seeing the company as a prime customer for DuPont paint

This advertisement for DuPont smokeless shotgun powder appeared in 1913, though Pierre du Pont and his cousin Francis Gurney du Pont developed the product in 1892. (Library of Congress)

products and other items. However, under the leadership of mercurial businessman William Durant, in 1920, GM found itself in financial trouble, a condition exacerbated by that year's recession. Major bankers refused to continue their support of GM unless Durant stepped down and du Pont assumed the leadership of the automaker. If only to save the considerable investment of the DuPont Company, Pierre du Pont accepted the presidency of the car company.

While he would only serve until 1923, du Pont's tenure was important. Foremost among his accomplishments was the introduction of cost accounting. He also got rid of a number of money-losing operations, like the small car companies that Durant had regularly acquired, such as Scripps-Booth and Sheridan, but that were, in fact, a drag on GM's bottom line.

In 1923, du Pont moved out of the presidency and assumed the position of chairman of the board, a post he held until 1929, and remained a member of the board until 1944. He was succeeded as president by Alfred P. Sloan, whose long tenure as president was made easier by the changes that du Pont had implemented.

Upon leaving the helm of GM, du Pont continued to sit on a number of corporate boards, holding directorships in companies as wide ranging as the Wilmington Trust Company and the Pennsylvania Railroad, but in general, he turned his focus away from business, becoming increasingly involved in philanthropy and public service. In the immediate aftermath of leaving the GM presidency, he played an active role in the campaign to repeal Prohibition. After that was achieved in 1933, du Pont turned his attention to the world of public education, helping establish the first state board of education in Delaware while also donating millions of dollars to the state's public schools. He made a point of donating funds to replace many of the dilapidated schools that served the state's African American students in the days before *Brown v. Board of Education*. Too, Pierre du Pont was a generous contributor to his alma mater, MIT, while also serving a lengthy tenure on its board of trustees. In addition, du Pont served in a number of public posts, including state tax commissioner. He also transformed the family's estate, Longwood Gardens, putting it under the control of a nonprofit foundation and opening it up to the public.

Pierre S. du Pont married the former Alice Belin in 1915. The couple had no children. He was at the family estate at Longwood Gardens when he died on April 5, 1954, from a ruptured aorta. He is buried in the Du Pont de Nemours Cemetery in Wilmington, Delaware.

DuPont Company

Originally a gunpowder company, E. I. du Pont de Nemours and Company (DuPont) was founded in 1802. Since that time, DuPont has expanded its chemical science undertakings to include 13 businesses divided among eight segments: agriculture, electronics and communication, industrial biosciences, nutrition and health, performance chemicals, performance materials, safety and protection, and pharmaceuticals. During the early 2000s, however, the company went through a streamlining process, with the sale of several of its divisions. Then, the company went through a restructuring with a merger in 2017. Due to its research and development efforts, DuPont was responsible for many technological innovations, including the development of nylon, Teflon, and Kevlar.

Éleuthère Irénée du Pont de Nemours (1771–1834), DuPont's founder, learned about the manufacture of gunpowder while working for the French government. After immigrating to the United States in 1797, du Pont built a gunpowder factory along Delaware's Brandywine River. With a reputation for the production of superior gunpowder, the company prospered.

After the founder's death in 1834, his sons, Alfred and Henry, expanded the business to include the manufacture of dynamite and nitroglycerine. With the management help of their cousins, Pierre S. du Pont and Thomas Coleman, DuPont's assets grew to \$24 million. As president, Pierre eliminated competition and increased the company's size by managing the purchase of 54 other companies. By 1905, DuPont controlled 75 percent of the U.S. gunpowder market, its assets were valued at \$64 million, and it had become one of the nation's largest corporations. In 1912, the U.S. government declared that DuPont was a monopoly and ordered a reduction of its size.

However, the company continued to grow during World War I (1914–1918). In addition, in 1914, it expanded into the automobile industry by purchasing 23 percent of all General Motors's stocks (which it held until 1951). After the war, explosives became less profitable. Consequently, DuPont focused research-and-development efforts to developing products for postwar consumer culture, such as

artificial fibers. In the 1920s, DuPont acquired the rights from a French company to produce cellophane in the United States. DuPont marketed it as a moisture-proof packing material for food and other items. During the decade, DuPont also produced rayon and polyester, which were used to make material for clothes.

In 1935, DuPont developers invented nylon, which had many uses, including in undergarments, stockings, tire cords, automobile parts, and brushes. During World War II (1939–1945), DuPont used nylon to produce parachutes, powder bags, and tire cords. After the war, DuPont also developed plastics (notably Lucite, a resin often used as a substitute for glass in paints and enamels) and synthetic rubber. Other notable inventions included Teflon (a nonstick resin used mostly for cookware) and Mylar (a thin, paper-like sheet of plastic with a variety of uses, including in the production of bags and book covers).

Between 1950 and 1970, many DuPont fibers, including Dacron (a type of polyester fiber that is wrinkle resistant and strong), Orlon (a synthetic acrylic fiber used for textiles), Lycra (elastic polyurethane fiber or fabric often used for close-fitting sports clothing), Tyvek (lightweight, high-density polyethylene fiber synthetic paper), Nomex (a heat-resistant metal variant), Qiana (a silky Nylon fiber), Corfam (artificial leather), and Corian (a solid surface material), were critical for the success of the U.S. Apollo Space Project.

During the 1970s, DuPont greatly reduced funding for research in an attempt to cut costs. According to analysts, during these years, DuPont relied too heavily on past inventions and concentrated too exclusively on the fiber market. Unfortunately, the consumer demand for artificial fibers fell during the 1970s, and the company experienced a period of decline. In 1980, however, a rededication to research led to the development of Kevlar, which revitalized the company. Kevlar fibers are light yet five times stronger than steel. Fabrics made of Kevlar are heat and puncture resistant. Many products are made from Kevlar, including heat-resistant gloves and clothing, construction cables, and automobile tire belting. However, the most profitable product to use Kevlar has been the bullet-resistant vest. Within a few years of the

invention of Kevlar, at least half of U.S. police forces wore Kevlar vests.

Since oil is needed to produce synthetic products, DuPont purchased Conoco (the second largest U.S. oil company) for \$7.8 billion. Other acquisitions included Remington Arms (a weapons company), New England Nuclear Corporation (a manufacturer of radioactive chemicals for medical research), and Solid State Dielectrics (a supplier of dielectric materials used in the manufacture of multilayer capacitors). During the next few years, DuPont continued purchasing other companies and sold a wide range of products, including oil, textiles, weapons, pesticides, pharmaceuticals, and electronics. In 1985 alone, DuPont spent over \$1 billion on research and development and employed over 6,000 scientists and engineers.

By the late 1990s, executives believed that DuPont had over extended itself, and they began making plans to sell off parts of the company. In 2001, DuPont sold its pharmaceutical business to Bristol Myers Squibb, and in 2004, DuPont sold its textiles business to Koch Industries. In 2013, the company sold DuPont Performance Coating to Carlyle Group (renamed Axalta Coating Systems). In 2015, DuPont sold its rubber business to Denka Performance Elastomers. Additionally, DuPont whittled down its major product themes to three areas: food, energy, and protection.

In spite of the streamlining, DuPont was still among the largest corporations in the world. From 2009 to 2015, Ellen J. Kullman (1956–), the first woman to be appointed DuPont's chief executive officer, was at the helm of the company, which operated in over 100 countries, employed 70,000 people, and reported yearly sales of about \$35 billion. In 2017, DowDuPont was formed after DuPont merged with Dow Chemical Company. Although DuPont had sometimes faltered, throughout its 200-year history, it had prospered the most from a dedication to the research and development of new innovative products.

Duprey, Ana Roqué de (1853–1933)

Scientist and educator Ana Roqué de Duprey, also known as “*Flor de Valle*” (“Flower of the Valley”), is known for her contributions to the founding of the University of Puerto Rico. She is considered an important and pioneering Puerto Rican scientist, feminist, and writer.

She was born on April 18, 1853, in Aguadilla, Puerto Rico, as Ana Roqué Geigel. She learned how to read and write by the age of three. Her mother passed away when she was only four, leaving her to be raised by her father, aunt, and grandmother, who were all educators. By the age of seven, she was sent to a regular school and graduated two years later. At the age of 13, she founded a school in her house and wrote a geography textbook that was later adopted by the Department of Education of Puerto Rico. In 1872, she married Luis Duprey and had five children, three of which lived to be adults. They later moved to the capital of San Juan, where she became the first woman permitted into the Puerto Rican Athenaeum.

In 1884, Roqué accepted a teaching position in Arecibo while also enrolling at the Provincial Institute, where she studied philosophy and science and earned a bachelor’s degree. After the United States invaded Puerto Rico in 1898, Roqué was appointed the director of San Juan’s college for teachers and later taught English in the city of Mayagüez, where she then founded a college. That same year, Roqué founded *La Mujer*, the first women’s-only magazine in Puerto Rico. Roqué also wrote several fiction and non-fiction books, including *Sara*, *La Obrera*, and *Luz y sombra*. In 1903, she was one of the principal founders of the University of Puerto Rico that included her college in Mayagüez.

Despite all of Roqué’s immense contributions to education reform and writing countless magazines as well as fiction and nonfiction books and articles, she is best remembered for her key role in Puerto Rico’s women’s suffragist movement. In 1917, with the help of Ángela Negrón Muñoz and Carlota Matienzo Román, she founded the Feminine League of Puerto Rico. This league was the first group in Puerto Rico with the primary focus on the advancement of women’s rights. In 1921, the group was renamed to the Suffragist Social League, and its focus was now on securing women the right to vote. By 1929, it was given to women who were able to pass literacy tests. Although it was a small step in the advancing of women’s rights, Roqué did not consider it a victory and continued pressuring the Puerto Rican Legislature to recognize the voting rights of all women. It wasn’t until 1935 that all women there could vote, two years after her passing.

Duryea, Charles (1861–1938) and Frank (1869–1967)

Charles and Frank Duryea invented the first successful gasoline-powered automobile, which was also the very first of its kind built in the United States. Their first car was successfully tested on the road in September 1893. It had four wheels, metal tires, a single cylinder, and a water-cooled gasoline engine.

In 1891, Charles had completed the design after being inspired by a gasoline engine that he had seen at an Ohio State Fair. With the help of his brother, Frank, he built a car and engine in a Springfield, Massachusetts, loft. Frank and newspaper accounts state that the

car's first test-drive was on September 20, 1893, despite Charles's statement that it happened in 1892. While Charles was in Illinois at that time, Frank did his test drive in Springfield, and he managed to have the vehicle move about 600 feet before its friction-belt transmission failed. However, there was no doubt that it had plenty of potential.

In November 28, 1895, the Duryea brothers entered their second and improved car, which had a two-cylinder engine and pneumatic rubber tires, into what was considered to be the first American automobile race. Eighty-nine entries were filed, but only six were able to participate due to the intensely snowy conditions of that early morning. With the challenge of traveling through a 54-mile round-trip course from Evanston to Chicago, Frank Duryea reached the finish line first after dealing with a series of repairs and malfunctions. At an average speed of about 7.3 miles per hour, Frank had won in just a little over 10 hours, along with a \$2,000 reward. Because the race had been publicized nationally, the car received mass recognition for its practicality, and it was predicted that this would be the end of horse-drawn transportation.

A year after Frank's victory, the brothers founded the Duryea Motor Wagon Company in Springfield, Massachusetts. It was the first American car company that built many cars at a time. In 1896, it manufactured by hand and sold 13 identical cars with the Duryea Motor Wagon brand. Because of this, it was considered the largest automobile factory in United States at that time. Unfortunately, in 1898, the company failed financially, and the brothers decided to part ways after a feud sparked between them.

Charles decided to manufacture three-cylinder automobiles and other vehicles, such as tricycles that were steered using a tiller. On the other hand, Frank continued his success by developing a limousine known as the Stevens-Duryea in the year 1904. His company produced 14,000 units but shut down in the early 1920s.

The car that Frank Duryea ran for 600 feet in Springfield, Massachusetts, resides in the Smithsonian Collection, donated in the year 1920.

Earmuffs

Earmuffs are objects that are designed to cover one's ears for warmth or for hearing protection. Earmuffs can be made of many materials, but they generally include a metal or plastic headband that goes over the head. The ends of the headband each have a cup or cushion that covers the ears. The materials for the cups or cushions vary widely and by use. Earmuffs used for warmth use soft, warm materials for the cups, while protective earmuffs generally use plastic or rubber cups.

Chester Greenwood invented earmuffs in 1873, when he was 15 years old. Greenwood lived in Maine and loved to ice-skate, but he found that his ears were often cold. He decided to invent his own type of ear protectors by asking his grandmother to sew flannel pads onto circular loops of wire that he wrapped around his head. Eventually, he would remodel the earmuffs with a better material and design.

The practical earmuff design and structure haven't changed for decades; only the materials have changed, depending on the season and current trends.

Eastman, George (1854–1932)

Entrepreneur George Eastman founded the Eastman Kodak Company, helping popularize photography for the masses in the late 19th century. His Kodak Black camera was the first camera to use roll film. Eastman also gained fame for founding the Eastman School of Music, a medical school at the University of Rochester, and the Eastman Dental Hospital in London. He also donated portions of his fortune to historically black universities like Tuskegee University and Hampton University.

Born in 1854, Eastman was the third child and only son of George Washington Eastman and Maria Kilbourn Eastman. He grew up on the family farm in Waterville, New York. The family moved to Rochester, a progressive New York town, in 1860. George Washington Eastman died in 1862, and Eastman's sister Katie died in 1870. After this second death, Eastman left school and went to work to support his mother, who took in boarders to earn money, and his remaining sister, Ellen.

In the 1870s, Eastman began to have success with his photography business. He patented the first practical roll film in 1884. Roll film differed from photographic plates in that it was protected from light exposure by a paper backing and because it was rolled into a cartridge. Originally called “sheet film” or “shot-gun cartridge film,” the paper-backed film allowed photographers to load film outside of a darkroom and to make multiple exposures without unwieldy plate changing. Eastman did not invent roll film; Peter Houston did so in 1881. But Eastman's patent allowed for more easily produced and usable film. In 1888, Eastman invented a box camera, the Kodak Black, to use the film. That same year, Eastman joined forces with businessman Henry Strong to found Kodak Company.

On the strength of his wildly popular photographic innovations, Eastman incorporated his company as Eastman Kodak in 1892. The company used a strategy pioneered by razor blade magnate King Gillette. The “razor and blade” strategy held that a company sold affordable products, like razors or cameras, and then sold items that went with them. In Eastman's case, he sold affordable cameras and made a fortune selling roll film.

Eastman never married. He donated over \$100 million to charity, including schools and colleges, in his lifetime. Severe pain stemming from a spinal disorder caused Eastman to kill himself in 1932. Eastman is the only person to have two stars on the Hollywood Walk of Fame, an achievement meant to signal the importance of roll film to the movie industry. He left his house to the University of Rochester, and in 1947, the university chartered the home to become a museum of photography and film. The George Eastman Museum still stands today as a monument to early American film history.

Eastman Kodak Company

Founded in 1888 by George Eastman, Eastman Kodak Company historically manufactured photographic materials, including film, chemicals, and paper. Generally referred to as Kodak, the company introduced products that allowed mainstream Americans to undertake personal photography. Kodak paved the way for recording history; it opened a path for recording vivid personal experiences and it drastically expanded the complexity of photography and its mechanics.

Eastman Kodak Company was founded by George Eastman (1854–1932) and Henry Strong (1838–1919) in 1870. Strong was working in his family's buggy-and-carriage business when he met George Eastman. Eastman was working on dry photography plates. They became partners and named the company Eastman Dry Plate. In 1884, Eastman and Strong concluded their partnership; however, the company had just experienced an expansion that resulted in the creation of “roll film.” This invention allowed Thomas

Edison to develop the motion picture camera. In 1888, Eastman invented a box camera that became the cornerstone of the new company. Kodak was registered as a trademark in 1888.

The company experienced success as it innovated its products throughout the years. In 1895, Kodak introduced a pocket camera. In 1900, Kodak introduced the Brownie camera, named after inventor Frank Brownell. Brownies were the first truly affordable, easy-to-use camera. The Brownie also pioneered the idea of a “snapshot” for Americans, who previously only had pictures taken in formal settings by professional photographers. The Brownie’s design was based on a cardboard box body, simple lenses, and roll film. The first Brownies were sold for \$1. The Brownie 127, which had a Bakelite body and was marketed between 1952 and 1967, was one of the most popular cameras ever sold.

As Eastman Kodak Company expanded, so did its presence in New Jersey and Tennessee. Also, it played a role in World War II, signing contracts with the U.S. military. In 1976, Kodak offered the Kodamatic instant cameras as part of an effort to increase its product selection. In 1986, Kodak introduced the first megapixel sensor for cameras, opening the market to digital photography. Five years later, Kodak offered the first single lens Professional Digital Camera System. In 1994, Kodak manufactured the Apple Quick Take, a digital camera for everyday use. In 2003, Kodak acquired Algotec Systems, an Israeli company, which performed digital management and storage of medical images.

In 2007, Kodak sold the Kodak Health Group for \$2.35 billion, money that it used to pay down debt. In 2009, Kodak announced a job reduction of 4,500 jobs. Sales decreased sharply, leading Kodak to stop producing certain products, such as Kodachrome color film. In 2012, the company filed for Chapter 11 bankruptcy protection, and the aftermath resulted in Kodak’s targeting of commercial customers by offering graphic communications, packaging, and functional printing. As the company had expanded, it had failed to develop a marketing plan to support its business model, and as new technology had arrived, it faced tremendous losses and litigation, and it struggled financially.

Kodak also faced competition from Sony, Canon, and Fujifilm, but mostly by smartphones. Also, its dependency on third-world companies affected it negatively: it could not maintain sufficient control over its suppliers’ mass production.

The company has focused on reconstructing its business around digital printing and making presses and technology to print documents, publications, and product packaging. Kodak is targeting the packing industry as its base for reconstruction by offering smart packaging. Its flexographic solution is a strategy for growth. Industrial packaging is in demand in countries such as China, Brazil, Russia, and India.

Edison, Thomas (1847–1931)

The scope and variety of Thomas Edison’s inventions put him in the pantheon of great American innovators alongside Benjamin Franklin and Nikola Tesla. Nicknamed “the wizard of Menlo Park,” Edison can be credited with the invention of the phonograph, the motion picture camera and the first practical lightbulb. Less well known is his invention of a stock ticker, an automated vote counter, and innovations in sound recording and telecommunications. Edison enhanced his ability to innovate with collaboration—particularly at Menlo Park, the nation’s first industrial research laboratory.

Born to Nancy Mathews Elliot and Samuel Ogden Edison Jr. in 1847, Thomas Edison’s family moved from Ohio to Port Huron, Michigan, when he was seven years old. As a boy, he contracted scarlet fever,

complicated by an ear infection that left him hearing impaired. As a result, he struggled in school. Teachers believed he was simpleminded, an impression reinforced by a speech impediment (undoubtedly a complication of his near deafness). Later in his life, he maintained that a train conductor who threw him out of a boxcar when his makeshift chemical laboratory caught fire caused his hearing loss. Edison might not have understood the root of his disability, or perhaps he preferred the more colorful story. His mother removed him from school before his first year of formal schooling was out and educated him at home. Later in his life, he was told that his hearing loss was most likely otitis media, an affliction that could be fixed with surgery. Edison refused the surgery, arguing that hearing might destroy his ability to think.

At 16, Edison took a job as a telegraph operator for the Grand Trunk Railway in Canada. It was on this job that he set up that makeshift laboratory in a boxcar. He lost the job when he nearly caused a train collision. Afterward, he turned his full attention to chemistry, though he continued to work as a “tramp telegrapher” through the Civil War.

In 1866, Edison moved to Louisville, Kentucky, where he worked for the Associated Press and Western Union at night. This left his days open for inventing. In 1869, engineer, explorer, and inventor Franklin Pope took Edison under his wing, allowing the young man to live in the basement of his New Jersey home. The two men founded Pope, Edison and Company Electrical Engineers. Edison invented a one-wire telegraph or stock ticker. Edison also earned his first patent in 1869 for the electrical vote recorder. Edison sold this invention and other telegraphic innovations, most notably the quadruplex telegraph, to Western Union and used the money to establish a research laboratory at Menlo Park, New Jersey, in 1876.

The burgeoning inventor hired a number of assistants and employees, including Swiss clockmaker John Kreusi and Charles Batchelor, an English mechanical engineer. In 1877, Edison invented the phonograph, earning him the nickname “the wizard of Menlo Park” from Americans who thought the phonograph just short of magic. Edison patented the phonograph the next year but did little to promote it until Alexander and Chichester Bell and Charles Tainter

produced a similar device, the gramophone, in the mid-1880s.

In 1878, Edison founded the Edison Light Company to produce a commercially viable lightbulb. In 1879, electrical engineer William Hammer came to work for Edison. The two men collaborated to improve lightbulbs and invented the incandescent lightbulb, solving the problems of earlier types. The next year, Hammer became the chief engineer for the newly formed Edison Lamp Works. Hammer would go on to be chief engineer for the English Edison Light Company, which built an electrical station in London, England.

In 1880, Edison established the Edison Illuminating Company to provide electric light to the masses, putting him in competition with gaslighting companies. The company’s Pearl Street generating station switched on two years later and provided electricity to 59 customers in Manhattan. The rest of the decade found Edison championing his direct current (DC) delivery system, putting himself at odds with George Westinghouse and others’ support of alternating current (AC). Edison maintained that AC was dangerous and would kill people, particularly if used incorrectly. Edison proved correct in this surmise when a number of people were killed by AC in 1888, causing a public outcry against it and the perceived recklessness of companies that used it. Though Edison continued to attack AC, the tide of public opinion gradually changed. The so-called war of the currents fizzled in 1892, when Edison was forced out of his electrical company and J. P. Morgan was installed at the renamed General Electric. Edison suffered another setback when the 1893 World’s Fair decided to electrify with AC. Edison continued to fight for DC, staging a series of AC electrocutions that culminated in the 1903 filmed execution of an elephant named Topsy.

From the “war of the currents” came the now-famous feud between Nikola Tesla and Edison. Tesla, who briefly worked for Edison, first at his machine works and then at one of his power plants, took the AC side of the struggle, arguing that it was more efficient. Tesla also objected to the manner in which Edison monetized and publicized his inventions. Certainly, Edison died a famous millionaire while Tesla spent his life in obscurity.

Edison's Menlo Park laboratory enjoyed so much success that by the time it was a decade old, it had expanded to fill two city blocks. An 1887 newspaper article claimed that Edison's laboratory contained over 8,000 types of chemicals and every type of wire, screw, and needle in existence, as well as more esoteric materials like peacock feathers, cocoon silk, and shark teeth. Edison's facility proved a fertile ground for innovation, giving rise to over 1,000 patents for a wide variety of inventions, including a fluoroscope for taking x-rays and the Kinetoscope, an early motion picture camera.

Indeed, Edison's Kinetoscope spawned an entire industry: motion picture or movie making. Edison demonstrated his moving pictures in the mid-1890s in New York and Europe. In 1894, the inventor established Edison Studios, first as Edison's Black Maria in New Jersey. In 1901, the studio moved to Manhattan and six years later to the Bronx. Edison delegated control of the company to others and played no part in early movie making. The studio would make over 1,200 films, 54 of which were feature length. Many of the films are considered classics of film history, including *The Kiss* (1896), which featured the first on-screen love scene, and *The Great Train Robbery* (1903), the first Western.

During his long career, Edison also investigated mining and cement production with his Edison Ore Milling Company and battery technology with the Edison Storage Battery Company. Edison also collaborated with Harvey Firestone and Henry Ford to establish an American supply of rubber.

Edison married twice. In 1871, he married Mary Stilwell, a 16-year-old employee. The couple lived in Menlo Park and had three children: Marion, Thomas Jr., and William. Mary Edison died in 1884 from complications stemming from a brain tumor and the morphine she took for pain. Less than two years later, Edison married Mina Miller, daughter of inventor Lewis Miller. They moved to Llewellyn Park, also in New Jersey, though the couple wintered in Fort Meyers, Florida, at a home they called Seminole Lodge. The couple had three children: Madeleine, Charles, and Theodore. Edison left the childrearing to his wives, preferring time spent in his laboratories to time spent with his family. William, Charles, and Theodore all became inventors and research engineers.

In his later years, Edison spent more time in Fort Meyers, Florida. Henry Ford, who began his career working for Edison, lived in the house next to Seminole Lodge, and the two men belonged to the same community service organization, the Civitan Club. In 1930, not long before he died, Edison opened the Lackawanna Railroad, an electrical (DC) railroad in New Jersey, and drove the first mile of the train's inaugural journey.

In 1931, Thomas Edison died from diabetes complications at his home in New Jersey and was buried on the grounds. Since his death, he has been widely honored as one of America's greatest inventors. Lakes, colleges, ships, asteroids, and towns have been named after him. Companies still bear his name, including Southern California Edison and the Edison Portland Cement Company. It is difficult to overstate Thomas Edison's influence on American society.

Electric Iron

American inventor Henry W. Seely developed and patented the electrically heated iron in 1881. His signature can be found on over 100 patents, including some that belong to Thomas Edison's inventions.

Seely initially came up with his design of an electric iron in 1881 and applied for a patent for it the following year. His invention offered an alternative to the

This vintage illustration, ca. 1920, of an early electric iron illustrates its sleek, clean design. Inventor Henry Seely kept only one third of the rights to his patent, assigning the other two thirds to Samuel Insull and Richard N. Dyer, Thomas Edison's patent attorney. (GraphicaArtis/Getty Images)

heavy and difficult-to-use charcoal-burning and gas-heating irons of the 19th century. The electrically heated iron allowed for a much cleaner and faster workflow, since ash was easily spilled from the charcoal-burning iron to the clothes, and other irons had to be placed on a stove for reheating.

Together with his partner, Richard N. Dyer, Seely worked on a different design in 1883 because they had doubts about having the iron continuously plugged into an electrical circuit. They invented a cordless iron that could be reheated on an electrically powered stand.

During the 20th century, steam was the primary means of heating irons; however, Seely's concept of the electric iron proved to be a practical invention that we still use today.

Electric Lightbulb

Thomas Edison (1847–1931) has been credited for inventing the first successful incandescent lightbulb in 1879. The lightbulb changed the world in many ways. It replaced more primitive ways of lighting, and it transformed home life, entertainment, and work. In more recent years, critics, legislators, and researchers

have sought to make the electric lightbulb more energy efficient.

Before the invention of the lightbulb, towns and cities were lighted by gas lamps, and people in the countryside lit their homes with oil lamps and candles. Reading or doing any kind of intricate work with these types of light sources was difficult, because the light they produced was neither steady nor bright enough. Early inventors hoped that running an electric current through some sort of fiber would create a glow of light. Unfortunately, these experiments failed, because the fiber melted after a few seconds or minutes.

Edison, an American inventor and businessman, conducted research on more than 3,000 different fibers. He finally settled on a thin filament of carbon made by burning a thread of chemically treated cotton. With the help of his lab team, Edison realized that the filament would glow much longer if he placed it inside a glass globe from which all the air was removed. On October 21, 1879, after many attempts, Edison's lightbulb glowed for 13 hours before the glass cracked. Edison was then able to extend the life of the lightbulb dramatically by making the glass more resistant to heat.

Edison advertised his new invention by lighting Menlo Park, New Jersey, at night. The spectacle caused a great sensation. However, as a consumer good, the lightbulb was worthless without a supply of electricity. With the financial support of J. P. Morgan, Edison formed the Edison Electric Light Company, which began supplying homes in Manhattan in New York City with electricity in 1882. Edison's use of direct current (DC) required that he build generators on every city block. Nikola Tesla, one of Edison's former employees, invented a motor in the 1880s that produced alternating current (AC), which could distribute electricity more cheaply and over longer distances than DC. Although Edison dismissed AC as unsafe, it would eventually replace DC.

For many years, only the wealthy in large cities benefited from the use of electric lightbulbs. It took many years for the use of electricity in most homes to catch on, because the wiring of existing homes was expensive. It was not until the 1920s and after many new homes were built with electric wiring that many new consumer goods for the home became popular, including radios, refrigerators, vacuum cleaners,

electric irons, bread toasters, washing machines, and dishwashers. Many of the new appliances made housework easier.

Transportation was also changed as headlights were mounted on automobiles and trains, making night travel safer. By using a lightbulb to project a strip of photographs on a big screen, Edison gave birth to the motion picture industry, which revolutionized entertainment. Before the use of the lightbulb and electricity, U.S. industry used lamps for lighting and steam to power factory machines. Its transition to the use of the lightbulb extended working hours, and electricity made factory machines more productive.

In more recent years, energy-conscious critics of the incandescent lightbulb charged that it was wasteful. In response, the U.S. government passed a law that required bulbs as bright as earlier 40-watt bulbs to draw only 10.5 watts and those with the brightness of formerly 60-watt bulbs just 11 watts. By 2014, all incandescent lightbulbs were phased out because they could not meet the government standard, though fluorescent lightbulbs continued in wide use. In 2016, a team of researchers from the Massachusetts Institute of Technology (MIT) claimed that it had developed a lightbulb that was much more energy efficient than compact fluorescent bulbs (CFLs) and light-emitting diode (LED) bulbs.

Electricity, War of the Currents

The “war of the currents” was the name given to a series of disputes that occurred during the last two decades of the 19th century concerning how electrical

power would be distributed on a national basis within the United States. The disagreement erupted into a feud between Thomas Alva Edison (1847–1931) and Nikola Tesla (1856–1943), the inventors of the competing electrical distribution systems.

Edison, after developing a commercially successful electrical lightbulb in 1879, began working on a way to distribute electrical power to consumers as a replacement for the existing gaslighting system. In December 1880, he founded the Edison Illuminating Company, and by late 1882, he had a generating station in New York City that provided electrical power to customers.

The system of electrical power distribution (transmission) that Edison developed was a direct current (DC) system. In a DC circuit, electrical current flows in only one direction and has a constant polarity. Edison's DC system worked well, and by the mid-1880s it had become the national standard. Edison earned many royalties from his direct current patents, which included an electrical utility meter that measured how much power a customer used.

One of the main technical drawbacks with the Edison DC system was that the voltage could not be easily changed for use with different electrical loads. This meant that most practical electrical applications in use at the time, which included lights and motors, needed their own separate power supply lines to provide the correct voltage.

A competing electrical transmission system was alternating current (AC), which had been developed in Europe during the 1880s by a number of electrical pioneers. The earliest AC systems in the United States used extremely high voltages to distribute power, and because of this, they were prone to sparking. A number of deaths were caused by the high-voltage lines, and there was widespread belief that the power companies were deliberately putting the public at risk.

Tesla knew that AC was more efficient at transmitting electrical power over longer distances and believed that the inherent problems with the distribution system could be mediated. However, Edison argued in favor of DC power distribution, citing the dangerous voltages used with AC power transmission systems. But Edison also had a monetary stake in the

outcome of DC versus AC, and he was not keen on the prospect of losing market share for electrical distribution.

In 1886, William Stanley Jr. (1858–1916) successfully provided electricity to a town with alternating current. The “Great Barrington Electrification” took place on March 20 in Great Barrington, Massachusetts, where Stanley had set up a complete AC power system that included a 500-volt generator and his new step-up and step-down transformers. Stanley demonstrated that AC could be used safely and that it could provide electricity to more customers than a DC system of the same size.

In 1887, Tesla filed seven patents for his complete polyphase AC system, which included transmission lines and generators and transformers. George Westinghouse (1846–1914) believed that Tesla's system was capable of producing long-distance power transmission and purchased Tesla's patents, offering Tesla a share of stock in his company.

By now, Edison realized that his DC power system was up against stiff competition. His reaction was to show how dangerous AC power could be. A number of people entered the fray on both sides of the AC/DC current war, including electrical engineer Harold Pitney Brown (1857–1944). Brown unsuccessfully lobbied to reduce the voltage of existing AC power transmission lines after several people in New York were killed by electrical shorts and arc lightning from AC power lines.

However, Brown had no qualms about animal welfare. Instead, he publicly electrocuted several dogs to show how dangerous AC was. When he heard that New York had decided to use death by electrocution instead of hanging for death sentences, Brown addressed the committee tasked with the chore of deciding on whether to use AC or DC and electrocuted a horse and several cows using 750-volt AC power. The committee was convinced, but it recommended using a higher voltage for human executions.

On August 6, 1890, convicted murderer William Kemmler (1860–1890) became the first person to be electrocuted to death. Brown had surreptitiously purchased the Westinghouse AC generator that was used in the botched execution, which lasted for nearly eight

minutes and produced such a horrible scene that electrocution became known as “Westinghousing.”

Westinghouse underbid rival company General Electric and got the contract to electrify the 1893 Chicago World’s Columbian Exposition, which was the first fair to be lit by electricity. Westinghouse was able to keep his price low because an AC power distribution system is more efficient than a DC system and requires less wiring, making it more cost-effective. The “City of Light” was illuminated by more than 100,000 incandescent lightbulbs powered by a dozen AC generators, and the Electricity Building housed several AC power exhibits.

The “war of the currents” continued into the 20th century. On January 4, 1903, Topsy the elephant was electrocuted at the Luna Park Zoo on Coney Island, New York. Topsy was shot through with 6,600 volts of AC, which instantly killed her. The gruesome spectacle was documented and released as an Edison film, *Electrocuting an Elephant*.

Electrification, Urban

Electricity is commonly transported to cities to power consumer appliances. Most of these appliances serve to provide light, automate processes, send information, or entertain. Power transmission is the transportation of electricity by bulk to be distributed to individual customers. Electricity is produced in power plants and transported through power lines in high voltage to prevent power loss. The voltage is then lowered into cities for consumer usage. Most cities have energy transmitted through alternating current; however, there are different methods to transfer electricity, including high-voltage direct current, which is used to send power over long distances. This electricity is sold by usage amount or time and measured in megawatts.

Most power is stored in power plants through various means. The most common method of storage is dammed hydroelectricity, which stores electrical energy as potential energy by pumping water against gravity. The potential energy created is then released, to be converted back into electricity. This method is used to store energy when it is not needed and release energy when there is a higher demand. This is done to provide a consistent amount of energy to cities. In cities, electricity is stored in batteries. Batteries use the energy transmitted through power lines and convert it to potential energy that is stored in containers. Most batteries store potential energy by polarizing chemical structures within their containers and then release a direct current through the appliances connected to them. Batteries are used around cities to transport and use energy without the need to be connected to power lines.

In the early days of energy transmission, energy was distributed in different voltages. This was because different appliances in cities needed different voltages. Because of this, energy generators had to be close to provide energy. There were specific lines for light, appliances, and rail transportation. Most of these early technologies of electricity were developed and used in Paris, London, Germany, and Rome—for example, the electromechanical generator made by Ernst von Siemens in the 1860s. One of the first companies to supply electricity as a utility was the California Electric Company in San Francisco in 1879. The utility

supplied power for light. During this time, the arc lamp was rising in popularity within industry, prompting San Francisco City Hall to be lit up in 1880.

In 1882, the Edison Illuminating Company began operation of the Pearl Street Station in Manhattan, New York City, the nation's first central electrical power plant. The Pearl Street Station used the new system of a centralized, direct current power station and served several businesses through an underground line. Likewise, this was the first introduction to the United States of an organized source of power, measurements for power usage, and power switches. In 1886, William Stanley Jr. was hired by Westinghouse Electric Company and perfected the closed core transformer. At this time, Westinghouse also purchased rights to the patents by Nikola Tesla of alternating current, which was widely used in Europe. Within that same year, the first American alternating current system was created in Great Barrington, Massachusetts. This system had a step-up and step-down transformer, which shaped the way we now transport power. The system continued to be refined, and two years later the first alternating current power station for long-distance transmission went online in Portland, Oregon.

In 1890, Westinghouse had 300 alternating current plants. At this time, there were 1,500 direct current stations by Edison. There was, therefore, tension between power companies as the United States looked for a more universal source of electricity. In the end, it chose alternating current as its standard, putting in place the structure we use today. Alternating current proved more advantageous for induction motors, which were used to industrialize production. Likewise, the usage of step-up and step-down transformers supplied a universal system, while direct current, though less efficient, continues to power some devices.

In 1890, Westinghouse created the first hydro-power station. It used alternators that produced power of 3.5 megawatts, reducing the cost of energy production. By 1902, this format provided electricity for a fifth of the United States. Mine mouth plants, or plants placed close to coal mines, also began creating electrical energy, particularly in the coal rich regions of the United States.

From this time on, technology further improved throughout the United States. More hydro plants

were created to distribute enough power to cities. Previously, electricity had been used by industry and to provide light in public places in the United States approaching the 20th century. After World War I and World War II, the creation of government-run power plants and postwar prosperity made electricity widely available to the consumer. By the 1930s, electricity was distributed all over the United States.

By the 1920s, the creation of home appliances like the freezer, the television, radio, and the washing machine called for further distribution of electricity. This was especially true for light sources like the incandescent light and air-conditioning for businesses and homes. With the increased use of electrical appliances, circuit breakers and safer transformers were created to prevent fires within cities. This raised American living standards. Industry likewise was revolutionized by automating labor like rock cutting, loading, and treadmill transportation, making mass production easier.

In the 1950s, the creation of computing and the consumer use of more electric appliances prompted more demand for electricity. This prompted electrical companies to create programs that made it cheaper for consumers to buy electricity during off-peak times while charging more during active times. By this time, the increased number of coal and gas plants created problems with pollution.

To help meet energy demands, nuclear technology was harnessed to produce power. The Atomic Energy Act of 1954 encouraged research into nuclear energy and nuclear power plants. However, the Price-Anderson Nuclear Industries Indemnity Act in 1957 made it hard for nuclear power plants to be built after there were several meltdowns. And in the 1970s, several programs arose to encourage nuclear power plants, but after protests were held against them, they failed. The United States had 99 nuclear reactors in 2016.

As of 2015, the total energy use in the United States was up to 3.86 trillion kilowatt-hours. Of them, 38 percent accounted for residential use while 36 percent was for commercial and 26 percent for industrial uses. Air cooling continues to be one of the largest users of electricity in the residential sector, combined

with refrigeration, lighting, water heating, and television. Lighting is one of the largest factors in the commercial sector, while machine drives are the largest users of electricity in industry.

Because of the continuous need for power and electricity, cities have been exhausting sources of electricity and causing pollution. This has created an energy crisis. The increased use of fossil fuels has released carbon dioxide into the environment, causing climate change. Likewise, the continued use of fossil fuels has created a scarcity, increasing energy prices. We have been looking for alternative methods of energy that give us the energy we need but do not undermine the climate.

Alternative sources of electricity used in the United States have included solar energy, hydroelectricity, wind energy, geothermal energy, and tidal energy. The country has improved efficiency to reduce the waste of energy, and it is trying to transition from fossil fuels to more sustainable systems. The United States has also been encouraging the use of more energy-efficient products and subsidizing some, such as home solar panels or electric vehicles, to reduce its emissions from the use of fossil fuels.

Escalator

Escalators, while common today, were once considered exotic, reaching the status of tourist attraction in some mid-20th-century towns. In many parts of the country, people recall their families traveling for miles to visit department stores that had escalators installed. One such business, the seven-story Gus Blass company in downtown Little Rock, was the first in Arkansas to install an escalator, and it drew crowds from around the state. In 1950, *Chain Store* magazine featured it in a Westinghouse ad that claimed, "Each of the 'Limited Budget' Westinghouse Stairways is capable of carrying 5,000 passengers at 90 feet per minute." As if at a theme park, people stood in line to ride them.

The escalator concept is simple: a moving staircase carries people up or down using tracks and a conveyor belt while keeping each step level for the passenger to stand on. The first escalator type of apparatus appeared two years after the first passenger elevator. Patent number 25,076 was granted in 1859 to Nathan Ames (1826–1865) for an invention he called "Revolving Stairs." The continuous revolving belt on which the escalator steps were mounted allowed the machine to carry passengers up or down. Ames envisioned the future in his patent application: "... buildings may be constructed much higher than heretofore, as the previous objections to such structures will be obviated."

Ames's steam-driven Revolving Stairs design is generally acknowledged as the world's first escalator, though he never produced a working model. His prototype drawings had design flaws, including the necessity for passengers to jump sideways to get off. Soon, his vision was fine-tuned by several inventors who received patents for "moving stairways," including Jesse Reno and George Wheeler in 1892. Ironically, given the escalator's attraction for middle America in the next century, Jesse Reno created a new novelty ride for Coney Island based on his patented design, a moving stairway that elevated passengers on a conveyor belt at a 25-degree angle.

The escalator as we know it was patented in 1898, having been modified by Charles Seeberger. Seeberger worked with the Otis Elevator Company to produce

the first commercial escalator in 1899. At the 1900 Exposition Universelle in Paris, France, the Seeberger-Otis wooden escalator won first prize. After Otis purchased patent rights from both Seeberger and Reno, Otis combined, improved, and marketed various escalator designs.

In addition to producing today's recognizable escalator, Seeberger also coined the current terminology. To coincide with his display at the 1900 Exposition Universelle, Seeberger wrote that he took the word "*scala*" from the Latin, as in to scale a hill, adding a modern-sounding prefix and suffix. He intended the word to be pronounced "es-CAL-a-tor." By 1950, however, the Otis company's exclusive use of the word "escalator" ended when a court decided that it had entered public domain as a generic term and removed trademark protections.

Whatever their nomenclature, escalators typically come in several configuration options: crisscross ("stacked" escalators traveling in one direction per side, often used in department stores or shopping centers to minimize space requirements), parallel (up-and-down escalators, either side by side or separated by a distance, seen often in subway stations), and multiple parallel (two or more escalators together that travel in one direction next to one or two escalators in the same bank that travel in the other direction). Visually attractive spiral escalators are also being utilized in contemporary designs.

Modern refinements include the option of changing the up or down direction of the escalators depending on traffic patterns to accommodate such events as rush hour, stadium crowds entering or leaving an arena, etc. Escalators are also required to have moving handrails that keep pace with the steps as a safety measure so riders can steady themselves. Escalators are often located near elevators that wheelchair-bound or disabled people can use.

Escalators have the ability to move large numbers of people in the same physical space as a staircase. Except during very heavy traffic, there is no waiting time to board. They can be used to guide people toward main exits or special exhibits, and they can be weatherproofed for outdoor use. Escalators have one additional advantage over most modern technology. When they break down, the steps remain horizontal, allowing them to be used as conventional staircases while

most other conveyances become useless in a breakdown.

Ferris Wheel

The Ferris wheel was the main attraction at the 1893 Chicago World's Columbian Exposition. The 264-foot tall wheel could be seen towering above other fair-ground attractions even before visitors entered the park.

In 1890, the U.S. Congress decided that Chicago would host a fair in honor of the 400th anniversary of Columbus's discovery of the New World. Illinois chartered a corporation known as the World's Columbian Exposition to design and build the fair, and in 1891, the corporation appointed architect Daniel H. Burnham (1846–1912) to head the design committee.

At a meeting of architects and civil engineers, Burnham goaded his audience into designing a suitably impressive structure to provide a focal point for the fair that would outclass the Eiffel Tower, which had debuted at the 1889 Paris Exposition.

One audience member was George Washington Gale Ferris Jr. (1859–1896), an 1881 graduate of Rensselaer Polytechnic Institute. Ferris had worked for a New York firm for five years before founding his own companies: G. W. G. Ferris Engineering Company in 1886 and Ferris and Kaufman Engineers in 1890.

Ferris designed a revolving steel tension wheel that would be sturdy enough to endure hurricane-strength winds. The 250-foot diameter wheel was comprised of two separate wheels held together by struts and supported by a 45-foot forged steel axle that weighed nearly 90,000 pounds.

The first design that Ferris submitted to the fair committee was approved, but doubts about the wheel

made them change their minds. Undaunted, Ferris revised his drawings and resubmitted them in November 1892, along with \$600,000 that he had raised to fund the project. He won the concession, and the wheel was slated to be built along Central Avenue, on the fair's midway.

Time was short: Ferris had only four months to construct his wheel. The winter was exceptionally harsh, and steam had to be pumped into the ground to thaw it for construction. Piles were driven 32 feet into bedrock and overlain with steel beams, which in turn supported massive concrete piers that would hold the giant wheel.

The completed axle was delivered in mid-March and assembly began on the wheel. A 1,000-horsepower steam engine was used to power the wheel while a second engine was kept as a backup. The ride was also equipped with a Westinghouse air brake.

When the fair opened on May 1, 1893, the ride was still under construction. On June 9, it was successfully tested without any of the 36 wooden cars attached to the frame. The next day, workers began the final assembly process of hanging the 24-foot-long cars and completing the loading platforms. More than 3,000 Edison lights adorned the wheel.

On June 21, the Ferris wheel was opened to the public, and it quickly became one of the main attractions of the fair. People were amazed that something that seemed so fragile could support itself, let alone carry more than 2,000 passengers aloft at a time. The 50-cent fare allowed rides of two revolutions of the wheel, allowing passengers time to admire the midway or to turn their gazes toward the White City, so named for its neoclassical exposition buildings covered with stucco.

When the fair closed on November 1, more than 1 million people had ridden the wheel. It was dismantled in April 1894 and reassembled in Lincoln Park, where it reopened in October 1895. Ferris had partnered with streetcar magnate Charles Tyson Yerkes (1837–1905) to build a restaurant, theater, and rides. But the ride was not a financial success, and by 1896, Ferris was bankrupt. He died on November 22, 1896, of typhoid fever.

The wheel continued in operation at Lincoln Park until 1903, when it was dismantled and taken to St. Louis for the 1904 World's Fair. After another

A ferris wheel debuts at the 1893 Chicago World's Columbian Exposition. Invented by George W. Ferris, the amusement park ride proved popular. (Library of Congress)

disappointing financial performance, Ferris's wheel was dynamited on May 11, 1906.

Primary Document: Telegrams between Luther Rice and George Ferris Following the Successful Test of the Ferris Wheel (1893)

Planners of the Chicago World's Fair of 1893 wanted a structure that would rival the wonder that was the Eiffel Tower, built for the 1889 World's Fair in Paris. George Ferris proposed a revolving wheel with a 250-foot diameter that would carry cars of people in circles. Nothing like it had ever been built. Ferris had designed the wheel but was not in Chicago as it reached completion. The following are telegrams between Luther Rice and George Ferris upon a successful test of Ferris's wheel.

Chicago ILL June 9, 1893 To: George W. G. Ferris The last coupling and final adjustment was made and steam turned on at six o'clock this evening—one complete revolution of the big wheel was made—everything working satisfactorily—twenty minutes time was taken for the revolution—I congratulate you upon it—complete success—Midway [Plaisance] is wildly enthusiastic. L.V. [Rice]

Pittsburgh, PA June 10, 1893 To: L.V. Rice [sic] Ferris wheel Your telegram stating that first revolution of wheel had been made last night at six o'clock and that same was successful in every way has caused great joy in this entire camp. I wish to congratulate you in all respects in this matter and ask that you rush the putting in of cars

[June 10, 1893, side 2] working day and night-if you can't put the cars in at night habbitt [i.e. hobble] the car bearings at night so as to keep ahead. Please take [sic] the Changes in the posts at once and rush same through with all possible speed-will be in Chicago the first of the week. Geo W. G. Ferris

Folding Cabinet Bed

The folding cabinet bed is a bed that, when not in use, can be folded into a desk that also has compartments for storage. The folding cabinet bed was designed and created by Sarah Elizabeth Goode.

Sarah E. Goode was an inventor and entrepreneur who was born in Toledo, Ohio, in 1855. She was the second of seven children. Her father, Oliver Jacobs, was a carpenter, and after the Civil War in the United States, she and her family received their freedom and moved to Chicago, Illinois. She met and married Archibald Goode and had six children with him. Archibald himself was a stair builder and upholsterer, and the couple opened a furniture store together. Goode developed and patented the folding cabinet bed in 1885. Her idea of the folding cabinet bed came out of a necessity of the times. Most of her customers were working class and lived in small spaces without much room for furniture. Her invention was a precursor to the Murphy bed, which was

patented in 1900. She was also one of the first African American women in the United States to receive a patent. Goode died in 1905 in Chicago, Illinois.

Goode's bed was designed to fold into a desk. The bed is made with three sections. The center section has a rectangular frame, and its length corresponds to the length of the bed. The left and right sections are hinged to the center section on opposite sides. The hinged section is constructed so that when the bed is folded, it forms an upright box that holds the mattress inside. The sections can also be constructed to form a desk-like structure so it can be used when the bed is folded. When the bed is unfolded, one of the hinged side sections forms the headboard; it can also act as the table portion of the desk. Additionally, there are braces on each side of the bed to hold it in place while unfolded. The braces also are the sides of the desk. The folding bed also has drawers that can be used when the bed is either folded or unfolded. The part of the bed where the mattress lies

is supported just like that of any nonfolding bed. Usually a spring mattress is used for the folding beds, but any type of mattress can be used.

Primary Document: Patent for Folding Cabinet Bed (1885)

In 1885, Sarah Goode became the first black woman to obtain a patent from the U.S. government. Her cabinet bed is the forerunner of the modern Murphy bed and is still considered an ingenious space-saving piece of furniture.

SPECIFICATION forming part of Letters Patent No. 322,177, dated July 14, 1885. Application filed November 12, 1883. (No model.)

To all whom it may concern.

Be it known that I, SARAH E. Goode, a citizen of the United States, residing at Chicago, in the county of Cook and State of Illinois, have invented a certain new and useful Improvement in Cabinet-Beds, of which the following is a full, clear, concise, and exact description, reference being had to the accompanying drawings, forming a part of this specification.

This invention relates to that class of sectional bedsteads adapted to be folded together when not in use, so as to occupy less space, and made generally to resemble some article of furniture when so folded.

The objects of this invention are, first, to provide a folding bed of novel construction, adapted, when folded together, to form a desk suitable for office or general use; second, to provide for counterbalancing the weight of the folding sections of the bed, so that they may be easily raised or lowered in folding or unfolding the bed; third, to provide for holding the hinged or folding sections securely in place when the bed is unfolded, and, fourth, to provide an automatic auxiliary support for the bedding at the middle when the bed is unfolded.

My invention consists in the arrangements and combinations of parts hereinafter described, and pointed out in the claims.

In the accompanying drawings, Figure 1 is a perspective View of my improved folding bed folded together so as to form a desk, which is shown open. Fig. 2 is a partial vertical sectional view of the same, showing the desk closed. Fig. 3 is a longitudinal sectional view of the bed unfolded. Fig. 4 is a sectional view of the same on line m x in Fig. 3. Figs. 5 and 6 are views of portions of the bed in detail, referred to hereinafter.

Like parts are indicated by similar letters of reference throughout the several views.

The main frame of the bed I make in three sections, A B C. The center or stationary section, A, consists of a stout rectangular frame, of a length corresponding to the width of the bed, and of sufficient width to form, in connection with the folding sections B and C, when folded together thereon, a receptacle large enough to contain the necessary bedding. The folding sections B C are hinged to the stationary section A on opposite sides thereof, so that when unfolded the stationary section A becomes the middle portion of the bed, while the folding sections B C form the respective end portions thereof, the width of the stationary section A being thus included in the length of the bed when unfolded. By this well-known construction a full-length bed 60 may be obtained which will occupy but little vertical space when folded up. The hinged or folding sections B C are preferably constructed so as to form equal halves of the upright box which contains the bedding when the bed is folded, and they may be provided with suitable panels and trimmings to represent the lower part of an ordinary office-desk.

Then folded together, the bed has all the appearance of an ordinary office desk, and may be used

as such. The entire desk, being attached to and forming a part of the head-section of the bed, does not in any way interfere with the folding or unfolding of the bed, and by the novel construction thereof the contents of the desk will be very little deranged by the turning necessary in unfolding the bed.

Having thus described my invention, what I claim, and desire to secure by Letters Patent

I. The combination, with the stationary section A and the folding sections B C, hinged on opposite sides of said stationary section, of a suspended bed-ding-support, h, secured at each end to the respective folding sections B C, the automatic auxiliary

support E. and the jointed braces O, substantially as and for the purpose set forth.

2. The combination with the stationary section A, folding sections B C, and head-board a, of end pieces, c c, top board, d, and cover e, substantially as and for the purpose set forth.

In witness whereof I hereunto subscribe my name this 8th day of November, A. D. 1883.

SARAH E. GOODE.

Food Preservation

Food preservation is a technique to keep food from rotting after harvest or slaughter. It is used to prevent the rise of bacteria, fungi, or other microorganisms. Among the earliest techniques of food preservation are drying and fermentation. Current techniques include freezing, canning, irradiation, pasteurization, and the addition of chemicals. For example, plain vegetables such as green beans and spinach can cause food poisoning if not preserved the correct way. Pressure-canning these vegetables destroys heat-resistant germs that can cause food poisoning. Advances in packaging have played a significant role in today's methods of food preservation. Maintaining or creating nutritional value, texture, and flavor is a huge aspect of food preservation. Food preservation has become a very important factor in the food industry, since fewer people eat foods that come from their own countries or areas and consumers expect to be able to buy foods that are not in season whenever they would like.

Freezing is the primary method used to preserve food. Clarence Birdseye was the founder of the frozen food industry. Birdseye was an American inventor and entrepreneur born in Brooklyn, New York, on December 9, 1886. Birdseye set out on a five-year trip in Labrador in 1912. While out there, he noticed that Eskimos froze food in the winter because it was hard to gather good-quality food. Birdseye was amazed by their

freezing process, which included ice, wind, and a very cold temperature to freeze fish quickly. He noticed that though the fish was frozen, it was extremely good quality when thawed. He realized that the frozen fish in New York was not comparable to the frozen fish that the Eskimos caught, and with this knowledge, he changed the way food was preserved across the country.

Freezing methods of the time usually used higher temperatures, slowing the freezing process and giving crystals more time to expand. Freezing food faster produces smaller crystals, which cause less damage to it. Birdseye quickly began to wonder how the freezing process worked on other foods besides fish. Back in the United States, he started working on his invention, the "Quick Freeze Machine," which froze food based on the techniques he had learned from the Eskimos. Later, he started his own company, the General Seafood Corporation, which grew and expanded quickly. By the 1930s, the company put out Birdseye's frozen fish, meat, fruit, and vegetables and changed the way people stored, cooked, and ate their food.

Canning is another method used to preserve the food we eat. Canning involves heating food that is sealed in a jar or can to destroy any microorganisms that can cause food spoilage. Air is removed from the jar, and a vacuum is formed as the jar cools and seals. There are two different kinds of canning method. Water-bath canning uses a large kettle of boiling water

to heat the jars, which are held underwater at a temperature of 212°F for a specific period. This method is used to process fruit, tomatoes, pickled food, and high-acid foods. The other method is the pressure-canning method, and it employs a large kettle that produces steam in a closed compartment. The jars in the kettle reach a temperature of 240°F under a specific pressure, with a gauge on the jar cover. This method is used to preserve foods that are low acid, including meat and fish.

Nicolas Appert is the man responsible for the various prepared foods that we now have in grocery stores around the globe. Appert was born on November 17, 1749. He had no formal education but had an interest in food preservation at an early age. He taught himself how to pickle foods and brew beer. Appert was inspired by war when he invented his method. During the late 18th century when French troops took over neighboring countries, it became clear that the government would not be able to succeed if its armies could not transport food on long trips without risk of spoilage. The government offered a prize of 12,000 francs to anyone who could come up with a practical way to fix this issue for the soldiers. Appert was very determined to win this prize regardless of how long it took him.

During this time, there was little or no awareness of food chemistry, so Appert's work was trial and error for some time. His process was to heat foods to the temperature of boiling water using an autoclave, a device that uses steam under pressure to purify food or other items. Appert opened the world's first canning factory in Paris in 1804. In 1809, he was confident in his work of preserving foods and sent his invention to the government.

Appert's process of canning takes about five hours to complete. The food must be placed in sealed glasses that are immersed deep in hot water. With the absence of air, no new germs can get to the food. After the jars are heated, they are removed and sealed shut with corks and sealing wax and then again with wire. The heat kills most of the pathogens that may be in the jars, and it pushes most of the air out of them. This process keeps the food from spoiling for long periods as long as the seals are not broken. Canning is standard for soups, meats, jams, juices, syrups, dairy products, and vegetables.

Another popular method of food preservation, and the oldest, is drying—which involves drying out food at a temperature high enough to take out the moisture but low enough that it doesn't cook the food. In earlier times, drying food in the oven and using the heat of the sun were the most common techniques. But these processes took far too much time and were not always guaranteed.

Chemical pickling is a very popular method of preserving food that places it in an edible liquid that kills germs and other microorganisms. Common pickling aids include vinegar, oil, and alcohol. Many people heat the food that is preserved and then soak it in the aids. Eggs, cucumbers, peppers, and pickles are standard pickled foods.

Food preservation has helped our world prevent decay and spoilage in food, allowing us to store and use it in the future. In some countries, there is a surplus in food production, and in others, there is not enough, so both can benefit from food preservation. Food preservation increases the shelf life for many perishable foods. It is also important because it allows seasonal food to be available to everyone at all times. These methods help prevent the waste of food around the world due to spoilage or decay. They add variety to our meals because we can have many types of food available to us.

Fountain Pen

Lewis E. Waterman's version of the fountain pen, patented in 1884, uses a tube that is reliant on capillary action. The ink flows onto surfaces with ease and with

a fluid motion. Waterman's fountain pen became one of the most successful versions ever on the market. Early models of this pen were made of hard rubber and had 14-karat gold nibs.

Rumor says that the idea for this fountain pen arose when Waterman had to run back to his office after his fountain pen's ink had leaked over a contract he had to sign when he was working as an insurance agent. As he was about to return, one of his competitors took advantage of his absence and closed the deal. This motivated him to create a pen that didn't leak.

Fountain pens already existed then, but Waterman invented a better one. Most fountain pens of the day leaked. He experimented with different tubes and found that capillary tubes managed the ink best. Like all pens, his used gravity to move the ink, but the capillary tube slowed down the movement just enough to prevent it from leaking or spilling.

Just after his patent on February 12, 1884, Waterman sold his handcrafted inventions from the back of a cigar shop with a guarantee that each would last for five years. He also advertised his pens in a popular magazine known as *The Review of Review*. Since business was booming, he decided to expand, and in 1885, he and his business partner, Asa Shipman, founded the Ideal Pen Company. Unfortunately, the company was not successful, and Shipman severed ties with Waterman.

Without a business partner, Waterman made another attempt in his ventures and established the Waterman Pen Company in 1887. There were orders from across the nation and from overseas. Business continued to grow, and there was a large surge in popularity for his pens to the point that production had to be moved. In 1899, he further improved the pen with adjustments that fixed the problem of bubbles that formed whenever ink ran low.

In 1901, Waterman passed away, and the business fell into the hands of his nephew Frank D. Waterman, who continued to expand. About 350,000 sales were made each year, but there were occasional drops when competitors entered the market. The Waterman Pen Company closed in 1954 after some struggles. The French branch of the company, however, survived and became part of the Parker Pen Company in 2001.

Frasch Process

Mining sulfur fluidically, also known as the Frasch process, is a method invented by Herman Frasch in the 1890s. Before that, extracting sulfur was very difficult. Frasch proudly claimed that he had managed to overcome eight or nine months' worth of effort with three days' worth of process. The Frasch process was the main reason that his company, Union Sulfur, became the main competitor for sulfur extracting companies in Sicily, Italy, in the 1900s.

Sulfur deposits in Texas and Louisiana were accidentally found after attempts to find oil in those states, but they were under quicksand, an obstacle for existing extraction methods. Every attempt to dig for sulfur ended in failure, as quicksand filled any holes soon after they were dug. Frasch, who already had experience in extracting substances, especially oil, decided to try a new method. Sulfur has a melting point of 115.2°C, which is only 15.2°C higher than the boiling point of water, 100°C. Taking advantage of this property, Frasch decided to extract sulfur in liquid form instead of in solid form, which was harder to extract because of the quicksand.

The Frasch process is to drill a hole above a deposit and drop in special pipes before the quicksand can backfill the hole. Frasch's pipes had three layers: the outermost layer was filled with superheated water at 168°C; the melted sulfur would be drawn into the middle layer. However, melted sulfur proved too dense to be pulled out from the pipe, so further heating was necessary to loosen it. Hence, the innermost layer of the pipes was filled with hot air to further loosen the melted sulfur.

The Frasch process reduced the effort and increased the production of sulfur exponentially. He managed to

significantly reduce the time spent to extract the element, which had earlier been taken up by attempts to remove quicksand. A single well using the Frasch process outproduced the several hundred existing wells in Sicily that still used the old methods; as a result, Union Sulfur became the second biggest producer of sulfur in 1904 and dominated the sulfur industry.

When the patents for the Frasch process expired in 1908, many other companies appeared in the industry, increasing the competition. They are generally called Frasch companies because they all use the Frasch process. New Frasch companies appeared mainly because they were able to mine deposits that existing companies deemed too small. Even these small deposits allowed them to become serious competitors by using the Frasch process.

The Frasch process of mining sulfur fluidically completely revolutionized the sulfur industry and, in addition, created a new more competitive and globalized sulfur market.

Gas Transmission

In the 1880s, natural gas was a promising source of energy. George Westinghouse resided in Pittsburgh, a city seated on an abundance of natural gas. He contemplated how he could control it in the same way he had invented the air brake that controlled compressed air in trains. He developed a way to distribute gas in Pittsburgh after drillers had broken into a flow of natural gas in his backyard.

Despite the public’s fear of natural gas due to the potential danger of occasional explosions, Westinghouse found it intriguing. He hired workers to drill in his yard, and soon a burst of sand, dirt, and water

spewed from the ground. The volcanic eruption of debris soon weakened, and a steady stream of gas gushed out of the well. Westinghouse had to quickly think of a way to control it before further chaos ensued; he responded by developing a simple valve. Later, he had to take further action and implemented the use of a 60-foot-long pipe. Because of how dangerous the substance was, there were horrific moments where Westinghouse shot fire into the sky.

In the summer of 1884, he received his first major patent for a system to utilize and keep gas under control while it was under high pressure. After establishing the Philadelphia Company, he patented 38 new inventions that were related to piping, especially ones related to natural gas, in 1884 and 1885. He found better ways to dig wells, invented meters for measuring the gas, and preventative methods against leaks.

Using a design similar to that of his patented automatic air brake, one of his most important patents made operations with natural gas much safer. It was for an automatic mechanism that shut off the flow of gas once a certain pressure was reached. After that, the supply of gas continued at the push of a button by an operator.

Another useful piping mechanism that he invented allowed for a healthy distribution of gas to both public and industrial consumers. Because the pressure of gas is naturally strong and usually too high to use directly, he designed a pipe system that stretched for miles. The pipes were narrow but widened at certain intervals, reducing the pressure of the gas based on the time of use. This piping infrastructure was recognized as the first widespread natural gas delivery system.

With Westinghouse’s Philadelphia Company as the main supplier for Pittsburgh’s natural gas, he had realized the business potential for the substance. The Equitable Gas Company later became a subsidiary. Westinghouse became the ruler of the gas industry.

He then applied his knowledge of natural gas technology to develop the alternating current distribution system for electricity, another seminal innovation.

Today, natural gas is one of our most important and affordable resources. The technology that Westinghouse created made it easier for us to work with it: the dangers have decreased as efficiency has increased.

General Electric

General Electric (GE) is one of the largest American industrial corporations in the world. Founded in 1892 after a merger of Edison General Electric Company and Thomson-Houston Electric Company, the new company had its headquarters in Schenectady, New York. The company is currently located in Boston, Massachusetts. GE's operations are located in more than 170 countries and employ about 300,000 people. It primarily offers electronic and electrical equipment, aircraft engines, and financial services.

The company was originally founded as the Edison General Electric Company, one of the many companies that Thomas Edison founded or had interest in. J. P. Morgan and Anthony Drexel, both financiers, put together the deal first to merge Edison's electric companies into one and then to merge that company with Thomson-Houston. The newly consolidated company solved the major problem facing small electrical companies: that it was difficult to fund electric installations with their own patents and technologies. The company proved so successful that in 1896, it was one of the first 12 companies listed in the Dow Jones Industrial Average. It is the only original company still listed on the Dow index.

In 1900, GE created the first laboratory used for scientific research in the United States. Since then, many new inventions and ideas have come from GE's research labs, including the electric fan, voice radio broadcasting, the electric stove, the hermetically sealed refrigerator, "invisible glass," the electric locomotive, the Hotpoint range, the jet engine, the vacuum tube, the autopilot, the commercial use of radar, and the nuclear power plant.

Electrical devices changed society significantly, pushing the steam age of the 19th century into the electrical age of the 20th century. Many of GE's technological innovations fundamentally changed the way Americans lived. For example, the incandescent lightbulb used in cars and trains allowed for safe night

An aerial view of the General Electric Company buildings in Schenectady, New York, ca. 1907. The company was founded on April 15, 1892. (Library of Congress)

travel. Radio broadcasting became mainstream entertainment in the mid-20th century.

GE owns a plethora of corporations that focus on different operations. The list includes GE Aviation, GE Capital, GE Digital, GE Energy Connections, GE Healthcare, GE Lighting, GE Power, GE Renewable Energy, GE Global Research, and GE Transportation.

General Electric has been awarded and recognized in significant ways. The company has been ranked in lists such as the World's Most Admired Companies, the World's Most Valuable Brands, the World's 100 Most InDemand Employers, the Top Companies for Leaders, the Best Companies for Leadership, the World's Most Ethical Companies, the Best Companies for Working Mothers, and the Top 50 Employers for Women. Nonetheless, in the late 20th century, GE gained fame for its ruthless corporate restructuring, giving rise to a national trend for downsizing and laying off employees. GE also found itself embroiled in price-fixing scandals and was cited on numerous occasions for breaking Nuclear Regulatory Commission rules.

Goodrich, B. F. (1841–1888)

Benjamin Franklin Goodrich, a physician and industrialist, founded several rubber businesses, including the B. F. Goodrich Company (1880). Goodrich faced failure on several occasions, but his persistence helped his company survive. More important, Goodrich built a company dedicated to technological innovation. In fact, the formative years of the automobile, airplane, and space industries benefited from B. F. Goodrich's innovations.

Goodrich was born in Ripley, New York, on November 4, 1841. He graduated from Cleveland Medical College in 1861, and he worked as an army surgeon during the American Civil War (1861–1865). He resigned from the army in 1864 and practiced private medicine for about a year. In 1866, he left the medical profession permanently and entered the real estate business in New York City.

In 1867, he and J. P. Morris, his real estate partner, purchased the Hudson River Rubber Company. Neither man knew anything about the production of rubber, but they saw the purchase as a money-making opportunity. Goodrich learned about the rubber industry on the job. Unfortunately, due to worn-out mechanical equipment, the company failed. But the failure did not deter Goodrich. Still convinced of the great future of rubber, the partners purchased another rubber company in Melrose, New York, in 1868.

Due to intense competition, his second company was also in danger of failure. To save it, Goodrich moved it away from competitors to Akron, Ohio, in 1870 and named it Goodrich, Tew & Company (GTC). GTC focused mostly on producing fire hoses, billiard cushions, and belting, and it struggled financially for almost a decade. In an attempt to keep GTC alive, Goodrich infused it with capital from new investors and reorganized and renamed it Goodrich & Company in 1874 and then B. F. Goodrich Company (BFG) in 1880. Goodrich ran the company as both president and manager. But the work was too much for him, and it placed a strain on his health. He died on August 3, 1888, in Manitou Springs, Colorado. But the company survived.

An American bicycle fad and the rise of the automobile industry in the late 1800s provided BFG with profitable tire markets. In 1895, BFG established the rubber industry's first experimental research laboratory. Innovation led to new products for consumers and financial success for BFG. Some of its innovations included the first pneumatic (inflatable) tire for bicycles (1890), the first pneumatic tire for automobiles (1897), the first rubber sponge (1902), the first cord tire for automobiles (1910), the first synthetic rubber tire for automobiles (1945), and the first radial automobile tire (1965).

BFG was also a major producer of aircraft tires. For example, all World War I (1914–1918) American

aircraft used BFG tires. After World War II (1939–1945), BFG expanded its research and development focus to aerospace (aviation and space flight technology). Alan Shepard, the first American in space, wore a space suit designed by BFG.

Goodyear, Charles, Jr. (1833–1896)

Charles Goodyear Jr., a businessman, was the oldest son of Charles Goodyear (1800–1860), the inventor of vulcanized rubber. Besides helping his father with his rubber business, he helped launch the mechanized shoe industry. Much more of a business innovator than an inventor, Goodyear's contributions to shoemaking were significant.

Goodyear was born in Germantown, Pennsylvania, on January 1, 1833. His father's obsession with finding a way to vulcanize rubber rather than earning a daily wage left the family destitute. However, after many attempts, his father was successful, and he patented his invention in 1844. Goodyear learned about the power of innovation from watching his father, and he learned about business by helping him sell licenses to manufacturers so that they could legally use the same process for making rubber. He also helped his father make, sell, and distribute rubber goods. After his father died in 1860, Goodyear spent the rest of his life overseeing Goodyear rubber patents, which generated income.

In addition, Goodyear extended his business interests to shoemaking. Handmade shoes were expensive because the process was time-consuming and labor-intensive. The earliest attempts to incorporate machines into shoemaking (driven by human hand or foot power) did not significantly increase production. By the mid and late 1800s, however, thousands of patents had been granted, and a variety of steam-powered and electric

machines were in use. Many inventors had attempted to adapt sewing machine technology to shoemaking. Unfortunately, most of the inventions suffered from performance flaws and frequent breakdowns. Goodyear saw a business opportunity, and he embarked on a mission to build and sell improved shoemaking machines. He began by purchasing the rights to several patented machines and then hired skilled inventors to improve them. By the 1870s, Goodyear had built factories of the Goodyear Boot & Shoe Machinery Company in both England and the United States. But innovation was expensive and, unfortunately, his company was not able to sell enough machines to make a profit until after his retirement in 1888.

Perhaps his greatest contribution in the shoe industry was overseeing the production of the Goodyear shoe welt machine. Several shoemaking processes were common, but handmade welt shoes were among the most expensive and typically custom made for the wealthy. A welt (usually made of leather) served as an attachment point for the sole of a shoe. His process made it possible for shoemakers to resole shoes and extend the lifespan of shoes by years. Goodyear's machine cut the price of producing welt shoes dramatically (from about 70 cents a pair to about 10 cents). In short, Goodyear's improved machines revolutionized the shoe industry by making it possible to mass-produce better shoes at lower prices. In poor health the last years of his life, Goodyear died on May 22, 1896.

Hallidie, Andrew Smith (1836–1900)

Andrew Hallidie invented the cable car, a motorless vehicle pulled along a track by a strong cable rotated off board by a powerful motor, in San Francisco around

1873. He was born in London on March 16, 1836. His grandfather was an educator from Scotland and a soldier during the Napoleonic wars, and his father, Andrew Smith, owned the patent for wire rope cable.

Hallidie's training was of both mechanical and scientific character. At only 10 years of age, he successfully constructed an electrical machine. At 13, he began working closely with his brother in a machine shop, and in 1852, they left for the United States. However, the father returned to England in 1853 while Hallidie remained in California, engaging in odd mining jobs. During this period, he designed several types of machinery to make mining work easier.

Hallidie abandoned mining in 1857 and returned to San Francisco with some of the machinery he had built. He began designing suspension bridges and became famous. In 1867, Hallidie obtained his first patent for the invention of a rigid suspension bridge. More patents followed. In 1871, he completed plans for propelling streetcars using underground cables. The first cable car was eventually tested on August 2, 1873. On April 24, 1900, Hallidie died of heart disease at his San Francisco residence as one of the city's most distinguished citizens.

Cable cars became popular due to their extraordinary capabilities. The cars overcame particular challenges, crossing waterways with minimum infrastructure as compared to other modes of transport such as buses and railways. Constructing transport infrastructure through such a terrain is costly, and cable cars solved the problem, as they could easily pass over mountains and steep slopes. The unique ropes used by the system could easily blend with the environment. Thus, the surroundings were only slightly affected and retained the beautiful scenery that was a tourist attraction. Additionally, they were more convenient compared to horses, which worked for only a few hours and had to be fed, receive medication, and rest, among other obligations.

In 1947, Mayor Roger Lapham decided to forbid all cable car lines to minimize operation costs. His intention was prompted by the growing popularity of buses, which appeared to be cheaper in terms of maintenance. A lobbying group began a public campaign to mobilize stakeholders and city leaders by emphasizing the importance of cable cars. In their argument,

they suggested that the intrinsic value to San Francisco was higher compared to operational costs. Finally, they succeeded, and an amendment was made on the ballot entitled Measure 10. City newspapers covered the story widely. Additionally, the lobbyists received overwhelming support from the public, and celebrities all over the country supported their brilliant move. The business community agreed, adding that cable cars were one of the most popular tourist attractions in the city.

Harvard Computers

Also known as Pickering's Harem, the Harvard Computers were a group of women hired to process astronomical data for Edward Charles Pickering at the Harvard College Observatory. The moniker "Pickering's Harem" was a reflection of the consideration for female intellect at the time, since the Harvard Computers were viewed as secretaries rather than scientists in their own right. Their work was integral to the completion of the Henry Draper Catalogues. Their examinations of photographs taken by the Observatory's male astronomers (a field now known as astrophotography) led to many discoveries and laid the empirical foundations for larger astronomical theory.

Edward Charles Pickering was the director of the Harvard College Observatory from 1877 to 1919. He was tasked with completing the work of Henry Draper, which focused on a catalogue of all the stars in the visible sky. By 1881, Pickering realized that the volume of data coming into the observatory in the form of photographs of the night sky was exceeding his staff's ability to analyze and catalog. A progressive thinker in

terms of educational opportunities for women and, frustrated with male staff members, Pickering hired his maid, Williamina Fleming, to help catalog the photographs taken by astronomers in the observatory. Fleming had been a teacher before having a child and becoming a maid. She proved highly adept at the task of performing careful and precise calculations and developed a system of classifying stars by using letters to designate how much hydrogen could be seen in a star's spectrum, which became known as the Pickering-Fleming system.

In 1886, Anna Mary Palmer Draper, the widow of Henry Draper, made a generous donation to the Harvard College Observatory. Pickering used the money to hire a group of female computers to work under Fleming's direction. The group of women was tasked with finishing Draper's catalogue by scanning and measuring astronomical photographic plates and completing calculations on the positions and brightness of stars. The group—which included Annie Jump Cannon, Henrietta Swan Leavitt, and Antonia Maury—worked in a large room on the east end of the Harvard College Observatory's top floor. Between 1881 and 1919, more than 80 women were hired to compute and catalog data, many of whom were recent high school or college graduates. The women worked six days a week, seven hours a day, earning 25 to 50 cents per hour—less than most clerical workers of the time. Their duties included reducing the photographs, taking into account things like atmospheric refraction to render the images as clear as possible; cataloging the photos; making notes on exposure and regions of the sky, which were copied into tables to record the locations and magnitudes of stars; and measuring the brightness of stars (spectra) to determine the properties of celestial objects.

As a result of their work, Pickering was able to complete and publish the first Henry Draper Catalogue in 1890. The catalogue included more than 10,000 stars classified according to their spectra. Two decades later, the catalogue was revised to include new observations. The Henry Draper Catalogue was republished every year from 1918 to 1924. Ultimately, the Henry Draper Catalogues classified over 50,000 stars by temperature, which indicated the size and age of the star.

Though the Harvard Computers received almost no recognition during their lifetimes, they surpassed most of their male counterparts in their discoveries in astronomy and astrophotography. They also wrote and performed a play called the *Observatory Pinafore*, a spoof based on newspaper articles of their work and fashioned after the play *H.M.S. Pinafore*. The play was performed on December 31, 1929, and included Cecilia Payne, Henrietta Swope, Mildred Shapley, Helen Sawyer, Sylvia Mussels, and Adelaide Ames.

Many of the Harvard Computers went on to stake individual claims to fame in astronomy. Williamina Fleming, the original computer, became the first female curator of astronomical photographs at Harvard College Observatory in 1898, and the fifth woman and first American woman to become honorary member of the Royal Astronomical Society of London in 1906. Her discoveries included the Horsehead Nebula, over 10,000 stars, and the existence of white dwarf stars. Antonia Maury developed a classification system that anticipated the connection between temperature and luminosity, now called the Hertzsprung-Russell diagram, and became the first woman to have her name on the cover of the Harvard Annals. Annie Jump Cannon expanded on Fleming and Maury's work to develop the OBAFGKM classification system for stars, also known as the "Harvard classification scheme," which is still in use today. Henrietta Swan Leavitt's observations led to the discovery of a direct relationship between the period of Cepheid variable stars and their intrinsic brightness, leading to our modern understanding of the true size of the universe and tools for measuring cosmological distance. Her work also identified 1,200 variable stars and enabled astronomers to calculate how bright a star should be to determine its distance from earth.

Together, the work of the Harvard Computers served as the statistical basis for theoretical astronomy. Many of their individual accomplishments are integral to our understanding of the universe and nature of stars today. The photographic plates and catalogs created by the Harvard Computers are still used by astronomers today, and their work helped to establish the Harvard College Observatory as a well-respected observatory and program.

Though the Harvard Computers remain relatively unknown, their work powerfully suggests the value of women scientists.

Haynes, Elwood (1857–1925)

American inventor Elwood Haynes manufactured early automobiles and patented martensitic stainless steel in 1913. His automobile design is widely credited with being the first practical for mass production.

Haynes was born in October 14, 1857, to parents of English descent. He grew up in Portland, Indiana. Haynes's father was the local school commissioner, a lawyer, politician, and judge of the local county. Haynes's mother, a devoted Presbyterian, staunchly supported the prohibition of alcohol. Haynes's interest

in metallurgy came from his grandfather, Henry Haynes, who was a gunsmith and mechanic. With a move to the countryside of Indiana, Haynes could build a melting furnace with the help of his grandfather. Some of the metals Haynes experimented with were copper, bronze, and iron. When not experimenting with his furnace and alloys, Haynes was often found exploring the woods near his house and surveying the various plants and animals. He spent so much time outdoors that his parents nicknamed him “Wood.”

Haynes began his career as a superintendent for Indiana gas and oil companies. In the 1890s, like many American mechanical entrepreneurs, he began to work on automobile development. Haynes initially hoped to have a steam-powered vehicle but found too many limiting factors connected with how the vehicle would generate power, and he ultimately abandoned the plan for more practical and proven techniques. To power his new vehicle, Haynes ordered a two-cycle engine from the Stintz Gas Engine Company for \$255. This type of engine was primarily used in small boats, but Haynes found that he could adapt it to provide power to turn tires in an automobile. Initially Haynes wanted to use lightweight materials such as leather and wood to fabricate the carriage so that the most power could be derived from the engine. However, he found these materials were not rigid enough to stop the vibrations from the two-cycle engine and did not provide enough rigidity. Haynes leveraged his knowledge in metallurgy and could craft a new carriage comprised primarily of steel. He test-drove his car, named Pioneer, in July 4, 1894, in the town of Kokomo, Indiana.

Haynes formed a partnership with Elmer and Edgar Apperson in 1896 to create Haynes Automobile Company. Haynes applied his attention to the problem of metal corrosion in automobile manufacturing, mixing tungsten with chromium, steel, and iron. He named this new alloy “Stellite.” In 1912, he founded the Haynes Stellite Company.

Stainless steel proved to be a highly versatile alloy, useful in many different applications. Stainless steel beams gave buildings a stronger structural frame, allowing them to achieve heights that proved too structurally difficult for lesser metals. One of the characteristics of stainless steel was that it could keep its rigidity in higher temperatures, and therefore kept its shape

under stress. This ability was highly sought after by the railroad companies because they wouldn’t need to replace tracks as often. Industrial infrastructure was not the only application for stainless steel. Many utilitarian purposes in the consumer space were enhanced by a corrosion-resistant alloy. Such household items as pans, knives, and forks could reap the benefits. These resistant properties would prove to be very alluring for the downstream consumer, because this meant that they wouldn’t need to buy new household items as often. World War I demand for his metal alloy made Haynes a millionaire.

Elwood Haynes passed from congestive heart failure on April 13, 1925, in Jacksonville, Florida. Before his death, he was recognized for notable contributions to industry, but chief among those accolades was the gold medal he received for his work with the Apperson brothers, awarded by the National Automobile Chamber of Commerce of New York. It was while traveling on the award trip that Haynes contracted influenza. His accomplishments in the advancement of the American auto industry will forever be recognized. It only seems fitting that Haynes’s funeral and burial took place in Kokomo, Indiana, where he first test-drove his model automobile, Pioneer. He left such an influential and lasting impact on the state of Indiana and the auto world that the General Motors Company used his family mansion as a headquarters for many years. The mansion is now in the possession of the city of Kokomo and houses the Elwood Haynes Museum.

Heyl, Henry (1842–1919)

Henry Heyl is best known as the inventor of the modern stapler, a fastening device that drives thin metal staples through paper and folds the ends. This device

is now common in offices throughout the world and helps facilitate all manner of business. Heyl also invented an early movie camera called the “phasmatrope.”

Henry Heyl was born in Columbus, Ohio, in 1842 and became a member of the Franklin Institute, a science and education center in Philadelphia. He raised four children with his wife, Mary Knauff. Some of his other inventions of note are the phasmatrope, which was a glass tube that, using static electricity, could project illusions onto a screen. What was so notable about this invention was that it was one of the first instances in which a succession of photographic sequences could be interpreted as motion. Heyl’s work could have been one of the precursors to film.

In 1882, Heyl filed patent number 83,640 with the U.S. Patent Office, entitled “Improvement in Paper Fasteners.” As noted in the title of the patent, Heyl’s invention was not something uniquely new but an improvement on a device that had already been in use since the 1700s. Originally, the stapler, developed in France, was used to place ornate handmade staples on documents of the royal court. However, Heyl’s patent was for the first device that could simultaneously punch through a stack of paper, insert a wire staple, and clinch the staple by bending the ends inward. Thus, the advantage of Heyl’s design was that it could complete a series of three motions in one action. Through the bending of the staple legs, stacks of papers could now be held together in an organized fashion, enabling the user to be able to quickly cycle through documents without compromising the sequential integrity of the documents or the documents themselves.

In the 1870s, Heyl filed patents for paper boxes and a camera that created the illusion of motion he called the Phasmatrope. The Phasmatrope used sequenced glass transparencies mounted on a disk fitted with a shutter to create pictures of a couple waltzing. He presented his invention at the Philadelphia Academy of Music in February 1870, and again a month later at the Franklin Institutes. Heyl’s Phasmatrope and its projected photographic sequence can be considered a forerunner to the moving picture or movie camera.

Heyl died in 1919. While his Phasmatrope is considered an important step in the history of moving pictures, he is best remembered as the inventor of the modern stapler.

Ice Cream Soda

The history of ice cream soda is a dubious one, with several people claiming they invented the concoction. Some speculation dates back to 1862, when Philip Mohr claimed that he mixed soda water and ice cream to cool the drink. However, the commonly accepted originator, who also worked to popularize the drink, is Robert M. Green. In 1874, at the Semi Centennial Celebration at the Franklin Institute in Philadelphia, Green had been selling soda, which was a combination of carbonated water, sweet cream, and syrup. He unexpectedly sold out of cream and had to turn to ice cream instead. It was a massive success, multiplying Green’s sales 100 times over.

The evolution of the ice cream soda has shifted over time, with dozens of alterations. In the 1890s, some members of the church urged against drinking soda on the Sabbath day (Sunday) because of the glutinous way people ingested it. Thus, on Sunday, stores began serving their ice cream without soda but kept the syrups, leading to the popular ice cream alternative called the “sundae.”

Inman, George (1895–1972)

George E. Inman led a group of scientists who produced the first commercial fluorescent lamp in 1935. Inman worked for General Electric lighting laboratories in Cleveland, Ohio. He was issued patent number 2,259,040 for the fluorescent lamp on October 14, 1941, with a filing date of April 22, 1936. To speed up the process, he used the design of an existing tubular

incandescent lamp. European competitors and rival companies Westinghouse and Sylvania were also working on fluorescent lighting. In 1934, General Electric Co. Ltd. in London, unrelated to the American General Electric Company, had come up with an experimental green fluorescent lamp with a brightness of 35 lumens per watt. The news of the European company’s progress pushed the development of the GE labs in the United States.

Some companies had filed patents already, but GE kept control by buying a German patent that preceded Inman’s patent. GE paid \$180,000 for patent number 2,182,732, which had been issued to Friedrich Meyer, Hans J. Spanner, and Edmund Germer. Edmund Germer had successfully made a fluorescent lamp that emitted white light, unlike other previous experiments that emitted blue-green light. While other companies had fluorescent lamps on the market by 1938, none were as well received as GE’s fluorescent lamp. There may be arguments about who the actual inventor of the fluorescent lamp is, but GE with Inman were the first to introduce it to the market.

Inman’s fluorescent lamp, which used white phosphors, was stable and reliable. The fluorescent lamp designed by Inman was a long tube filled with gas at low pressure. As the electricity flowed through it, it excited the gas, causing ultraviolet light to be emitted. The cylindrical bulb is coated with a film that then turns the ultraviolet light into white light. Mercury vapor and a gas, usually argon, are now commonly found in the compact fluorescent lightbulbs (CFLs) that we use in our houses.

George E. Inman’s work continues to be used today. The first fluorescent lamps might have appeared in 1938, but today, CFLs are used all around the world. Light-emitting diode (LED) lights are also available, but the reliability, lamp life, and cheap production as well as energy efficiency of fluorescent lamps cause them to be one of the most common lighting choices.

Iron Ship with Revolving Turret

Swedish-born inventor John Ericsson was responsible for the completion of the USS *Monitor*, the first iron ship with a revolving turret. The *Monitor* fought at the battle of Hampton Roads on March 8, 1862, during the American Civil War against the CSS *Virginia*. The design of the ship was one that most people had never seen before; it looked nothing like ships that had fought previously. Its construction and innovative design changed the way that the U.S. Navy would construct its future naval ships forever.

John Ericsson was born July 31, 1803, in Värmland, Sweden, to a modest family. Ericsson, along with his brother Nils, were self-taught mechanics. They had never had any type of training or schooling prior. When Ericsson turned 17, he joined the Swedish Army, where he received training in various skills. In 1826, Ericsson moved to England after leaving the army. He began to pursue different engineering projects, and he became quite a popular engineer and inventor. Ericsson moved to New York City in 1839, where he began to work on the first U.S. Navy screw-powered warship, which became to be known as the USS *Princeton*.

On October 4, 1861, the U.S. Navy signed a contract that granted Ericsson only 100 days to complete the construction of the USS *Monitor*. The ship was officially launched for sail on January 30, 1862. Many ships built prior to the *Monitor* had been constructed with turrets but never any that were capable of rotating. Turrets were designed to protect crew members and to mount weapons, but with the design of the turret on the *Monitor*, it was now possible to block cannon shots because of its rounded shape, as well as to maneuver guns on board much more easily.

The *Monitor* was a ship designed like no other. It was 172 feet long, and from the beam, it was 41.5 feet. The hull was five-eighths of an inch thick, being heavily armored and protected from cannon fire. The gun turret on the deck was quaint but very protected, as it

had a removable smokestack and a small pilothouse. Eight layers of one-inch, iron-bolted plate held the turret together. A sound barrier was also provided inside the turret with the addition of a ninth layer of plate. Many of these components would later be introduced into submarine design.

On March 8, 1889, Ericsson died on the anniversary of the Battle of Hampton Roads. He was forever immortalized as one of the greatest naval engineers in the United States and most recognized for his work on the *Monitor*, although he engineered other inventions as well.

The *Monitor* revolutionized naval ship building by combining speed with armor defense in the same ship. This ship allowed for a more precise and strategic construction of new ships built for the naval forces. Many engineers and designers began to copy the design of the *Monitor* for their own warships. The rotating turret can be found on modern warships and is a valuable technological creation in naval history.

Ironing Board

The ironing board had its last major improvement in 1892, when African American inventor Sarah Boone was granted a patent on an improved design. Prior to Boone's improvement, W. Vandenburg had patented an ironing table in 1858. Boone's improvements made it much easier to iron sleeves, collars, and women's more intricately shaped garments.

Boone was born Sarah Marshall in 1832 on a plantation in North Carolina. During this time, North Carolina was not considered a free state, and the exact date of her birth is unknown. She married James Boone, who was a freedman with whom she had eight children. Before the American Civil War could begin, the family decided to move to New Haven, Connecticut. She became a dressmaker, and her husband worked as a brick mason.

As a dressmaker, Boone often found it hard to iron many of the garments, since the tools that then existed would not adapt to the different clothing she was handed. Boone decided to invent an ironing board that would make it possible for her to finally iron garments properly. The ironing board she created was a curved, narrow wooden board that made it possible to iron all sides of a garment.

On April 26, 1892, the U.S. Patent and Trademark Office issued Boone U.S. Patent 473,655 for the improvement of the ironing board. This was a great accomplishment for Boone, as she was one of the only African American women during this time to be granted a patent.

The improvements to the board made ironing quicker and more precise. The curves that Boone added remain in the versions still manufactured today. Two changes have been made to the ironing board since. The first is that the boards are no longer of wood but rather of metal. Making them is faster, and they last longer. The second change is that they are narrower and can fit practically anywhere. There are also half-sized boards that rest on tabletops, making storage easier for people living in smaller spaces and making small ironing jobs simpler.

Although modern fabrics have eliminated much of the need for ironing and therefore ironing boards, Boone's improvements changed the way that people ironed clothes for many decades. Boone died in 1901.

Jeans

If there is one single item of clothing that epitomizes the American way of life and culture more than any other, it is undeniably jeans. Once primarily regarded as the outfit of those who worked hard for a living, nowadays, they are a staple item in wardrobes worldwide, irrespective of gender, social class, economic background, economic considerations, or culture.

Jeans were originally the invention of German immigrant Levi Strauss (1829–1902). In 1848, Strauss moved to New York City with his mother and sisters to work at the dry goods stores that his two elder brothers already owned on Houston Street: “J. Strauss Brothers & Co.” (which would be renamed “Levi Strauss and Co.” in 1863). In 1853, he moved to San Francisco to open a branch of his brother’s shop with the aid of his brother-in-law, David Stern.

Despite the long-held belief (further reinforced by a pervasive Levi’s promotional campaign) that jeans were primarily designed with those attracted to the California Gold Rush in mind, the truth is that they were not produced until years after the peak of the Gold Rush. In San Francisco, Strauss realized that pants did not last long enough due to hard working conditions. Strauss’s first waist overalls were made of canvas, although he later decided to make them out of “*serge de Nîmes*” (what we know today as “denim”).

A Nevada tailor, Jacob Davis, perfected the pants made of Strauss’s cloth by adding metal rivets, but lack of funds prevented him from patenting his system. Davis next approached Strauss and offered to share the patent in exchange for Strauss’s coverage of the fees to apply for the patent. It would be on May 20, 1873, that they were jointly granted U.S. Patent 139,121.

The first jeans were either indigo blue or brown cotton (called “duck”), but the latter was soon discontinued. The blue color was the creation of chemist

Marlon Brando and his gang from *The Wild One* (1953), decked out in “bad boy” jeans. While jeans are currently considered mainstream clothing, in the 1950s they were a symbol of rebellion. (John Springer Collection/Corbis via Getty Images)

Adolf von Baeyer, who invented synthetic indigo dye, which earned him a Nobel Prize. Strauss’s pants were known until 1890 as “waist overalls.” In 1890, the same year that Strauss and his nephews incorporated the business, they were renamed “501s.” In the 1960s, they began to be called “jeans,” which is derived from the name of Genoa, the Italian city where the fabric originated. The use of the name “Levi’s” to refer to the jeans originated in people’s colloquial speech, not from the company.

Levi’s jeans first appeared in *Vogue* in the 1930s. It was in this decade too when Eastern residents came back home from holidays in California wearing jeans, helping to popularize them on the East Coast. In 1934, Lady Levi’s, the first Levi’s for women, were created.

In the 1950s, the pants were adopted by rebels as a symbol of their nonconformism.

So closely were Levi’s associated with rebellious attitudes that in the 1950s, they were banned in schools throughout the country, but especially in the East. In the 1970s, jeans were already being worn by people from all social backgrounds. In the 1980s, the first designer jeans were produced, starting with those manufactured by Calvin Klein.

A fire following the San Francisco earthquake of 1906 destroyed the jeans company’s headquarters and two factories, forcing it to move. Levi’s had started as a family business in a small store in New York City, and it has continued to be a family-run company for the most part. In the 1970s, shares in Levi’s were first

sold in the stock market, but the company is still owned and under control by the descendants of Strauss's four nephews to whom he bequeathed his company. Levi's had 17,000 employees worldwide in 2016 (1,300 in its San Francisco headquarters), and it also produces the brands Dockers and Slates.

Despite the fierce competition in the jeans market, Levi's has managed to continue being strong in the very field it created. To help identify genuine Levi's, the two-horse logo began to be attached to the pants in 1886; in 1936, the red tab was added to the left rear pocket. Even in the face of cheaper competing products, Levi's has stayed in the business by appealing to those who want the genuine article. So precious are Levi's that there have been reported cases of the jeans being used in lieu of currency in wartime and during the Cuban embargo.

Associated with the American way of life and, therefore, with capitalism during the Cold War, jeans would not be introduced to the USSR until 1957, and they were mainly worn by students or tourists. In 1999 *Time* magazine chose Levi's jeans as "the Fashion Item of the Twentieth Century."

Jockstrap

Jockstraps are male undergarments designed to support and protect the penis and testicles during athletic activity. Although jockstraps can vary greatly in style, they typically consist of an elastic waistband with an attached support pouch into which a plastic or metal cup may be inserted for added protection.

Jockstraps were created by C. F. Bennett in 1874. Bennett worked for a sporting goods company and initially intended jockstraps for use by bicycle riders, then commonly referred to as "bike jockeys," a term that gave jockstraps their name. Jockstraps rose in popularity and were soon regarded as a standard garment for men playing contact sports such as wrestling, football, and basketball. Jockstraps became so

common that the term "jock" was coined to refer to males who play sports.

Although use of jockstraps in sports has dropped since the 1980s because of the invention of compression shorts, they continue to be strongly associated with athleticism and male fashion.

Jones, Amanda T. (1835–1914)

Inventor, writer, and entrepreneur Amanda Theodosia Jones innovated the use of oil as furnace fuel and founded an all-woman canning business based on her improvements in food preservation.

Jones was born in East Bloomfield, New York, and attended the East Aurora Academy. She graduated at 15 and began teaching. She taught for four years, all the while writing and publishing poems. She contracted tuberculosis in 1859 and spent a year recovering at her mother's house in Wisconsin. Shortly after, she published her first of six books. She also embraced spiritualism, a religious belief in spirit communication that was popular in the mid-19th century.

In 1869, she moved to Chicago and began experimenting with food preservation. She invented the Jones process to vacuum-pack fresh fruit. She first patented her process in 1872 and eventually applied for four more patents based on improvements in her process. In 1880, she invented an oil burner for furnaces. Capitalizing on the increasing availability of petroleum oil, she intended the oil burner to generate steam for powering glass manufacturing.

Jones founded the Women's Canning and Preserving Company in Chicago in 1890. Because she was an ardent supporter of women's rights and woman suffrage, she used her company to create meaningful paid labor for women. Her all-female company failed after

three years, however, after which Jones moved to Kansas to live with her sisters.

For the rest of her life, Jones continued to improve oil burners and canning processes. In 1904 and 1905, she published a series of four articles on the “liquid fuel problem” for an engineering journal. She also continued to write and publish poems. She published her autobiography in 1910. She died in 1914, a victim of influenza.

Primary Document: “The Soldier’s Mother” by Amanda T. Jones (1867)

Americans in the 19th century did not subscribe to the more contemporary notion that the humanities and sciences were two entirely different fields of intellectual endeavor; thus, they did not believe that people who were “scientific” or technologically minded were unsuited or unable to also be poets, artists, or writers. Inventor and businesswoman Amanda T. Jones, founder of the all-female Women’s Canning and Preserving Company (1890) was also a songwriter and poet. The poem here suggests the Civil War’s profound influence.

The Soldier’s Mother

Awake, little daughter, awake!
The sad moon is weaving her shroud;
The pale, drooping lily-bells quake;
The river is sobbing aloud.
I wand your sweet face in my sight,
While I open my room to the night:
The torn clouds are flying, the lupine is sighing,
The whip-poor-will wails in affright.
There’s a shadow just marked on the floor—
Now soaring and breaking its bond;
’T is the woodbine, perhaps, by the door,
Or the blooming acacia beyond.
Oh, pitiful weakness of grief!
Oh, trouble, of troubles the chief!
When shades can assail us, and terrors impale us,

At sight of a quivering leaf.
I weep, little daughter, I weep;
But chide me not, love, for I heard,
Three times in the depth of my sleep,
The clang of a terrible word.

“Your Harry is dying,” it cried;
“Is dying” and “dying,” it sighed;
As bells that, in tolling, set echoes to rolling,
Till fainting sound ebbs like the tide.

Then the walls of my room fell away;
My eye pierced the distance afar,
Where, by the plowed field of the fray,
The camp-fire shone out like a star.
And southward, unhindered, I fled,
By the instinct of motherhood led;
The night-wind was blowing, the red blood was
flowing,
And Harry was dying—was dead!

I dreamed, little daughter, I dreamed—
Look! the window is lit by a face.
It is not? Well, how lifelike it seemed!
Go, draw down the curtains of lace.
It may be ’t was only a flower;
For fancy has wonderful power.
The loud wind is whirring—hark! something is stirring—
’T is midnight—the clock knells the hour.

The horseman had ridden all night;
His garments were spotted with gore;
His foot crushed the lily-bells white—
He entered the vine-covered door.
“Your Harry is dying,” he said:
The mother just lifted her head,
And answered, unweeping, like one who is
sleeping,
“Not dying, good soldier, but dead!”

Kellogg, William Keith (1860–1951)

William Keith (W. K.) Kellogg was a philanthropist, businessman, and founder of the Kellogg Company. He placed an indelible mark on industry and contributed to America's cereal craze. Born April 7, 1860, in Battle Creek, Michigan, Kellogg was the seventh of 16 children and the younger brother of John Kellogg, an eccentric physician and director of the Battle Creek Sanitarium. A member of the Seventh-day Adventist Church, Kellogg believed in the virtues of a healthy diet and worked to create a healthy breakfast alternative. He is best known for accidentally discovering the process for creating cornflakes. Because of Kellogg's ingenuity, the Kellogg Company has dominated the breakfast cereal industry since its founding in 1906, with its products manufactured in 18 countries and marketed across the globe.

Prior to the 1890s, the American breakfast consisted of porridge or gruel. To encourage better eating habits, sanitariums were created to serve as health facilities. The Battle Creek Sanitarium promoted the ideas of the Seventh-day Adventist sect and emphasized rest, exercise, and a vegetarian diet. Kellogg was hired as Battle Creek Sanitarium's accountant and manager of daily operations. He also worked to create a palatable meat substitute, which led to his famous discovery—cereal flakes. Kellogg stumbled on the flakes when he accidentally left wheat cooking on the kitchen stove. After the cooked wheat hardened, Kellogg wondered what could possibly be done to salvage what seemed to be a culinary disaster. He decided to roll out the hardened wheat and bake it. The result was wheat flakes.

Kellogg saw the potential profit to be made and believed it should not be sold exclusively to sanitarium guests. Unlike his brother, who welcomed visitors to witness firsthand the production of wheat flakes, Kellogg wanted to safeguard the trade secrets and objected to guests viewing the manufacturing process. His fears were realized when C. W. Post, a guest at the Battle Creek Sanitarium, created his own cereal after visiting the Battle Creek factory and became a competitor in the breakfast cereal industry. The success of Post angered Kellogg and widened the rift between him and his brother.

In 1898, Kellogg improved the flakes by using corn instead of wheat. The new and improved flakes were produced under the company name Battle Creek Toasted Corn Flake Company, founded in 1906 and renamed the Kellogg Company in 1925. Even though the company became a million-dollar success, tensions continued to grow between the two brothers, leading Kellogg to take the drastic step of creating his own company. He also gained exclusive rights to the Kellogg name. To distinguish his cornflakes from those of competitors, Kellogg placed his signature on each box and added the slogan "Beware of imitations. None genuine without this signature." Additional modifications were made to the ingredients to improve shelf life, and later, sugar was added to enhance the taste. Kellogg also utilized creative marketing methods that targeted children, such as gaining sponsorship from children's programming and including prizes with each box of cereal.

Kellogg used his great wealth to improve society and help those in need. His property in Michigan was donated to Michigan State University, and his horse ranch in Pomona, California, became the home of California State Polytechnic University at Pomona. In response to the Great Depression, Kellogg changed employee shifts from 40 to 30 hours per week; hence, he created four six-hour shifts. As a result, Kellogg hired more employees, which greatly helped the people of Battle Creek. In 1930, President Herbert Hoover made Kellogg a delegate to the White House Conference on Child Health and Protection. His experience inspired him to create the W. K. Kellogg Child Welfare Foundation with the objective of improving the health and education of children. Later, it was expanded and renamed the W. K. Kellogg Foundation, which is one of the richest organizations in the United States. Kellogg believed in helping those who were less fortunate and ensuring the success of future generations. To guarantee the foundation's longevity, Kellogg willed 60 percent of the company's interest to the foundation. Kellogg died October 6, 1951, due to heart failure.

Kelly, William (1811–1888)

American inventor William Kelly pioneered the Pneumatic Steelmaking Process. Harry Bessemer patented a similar process in 1855. A company purchased both patents and licensed them as Bessemer Steel. History remembers Bessemer, but Kelly's role in steel production innovation is relatively unknown.

Born in Pittsburgh, Pennsylvania, on August 21, 1811, Kelly studied metallurgy at Western University in Pennsylvania before beginning his career in the dry goods industry. At the age of 35, he became a senior partner in the Pittsburgh dry goods and shipping company McShane & Kelly. While traveling for the company, he gained an interest in the iron industry, which was in high demand due to a rapidly expanding cross-country railroad network and the development of mass production following the Industrial Revolution. He moved to Eddyville, Kentucky, where he purchased over 14,000 acres of timberland rich in carbon-free iron ore deposits. Alongside his brother and brother-in-law, he established Eddyville Iron Works using the property's deposits to supply ore for a steel forge while using the timber as charcoal fuel. As the timberland depleted due to the intense fuel demands of smelting the ore and forging the pig iron into steel, Kelly began searching for a means of improving ore refinement to save on charcoal costs.

At the time, iron was sold in three forms. Cast iron had a high carbon content, which made it strong but brittle. Wrought iron was cast iron heated in a low-oxygen environment to remove all carbon. Steel, the strongest variant, had intermediate carbon content and was produced by heating the iron slowly to high temperatures. This made the process expensive and therefore little used. There was no large-scale iron production, and all ironwork was produced by individual artisan foundrymasters in small batches.

William Kelly, shown here, coinvented the Bessemer process for the mass production of steel. William Kelly and Henry Bessemer independently discovered a method for injecting air into molten iron to transform it to steel. (Library of Congress)

In 1847, Kelly began experiments, first at Union Forge and then at Suwanee Furnace in 1851. He designed a cupola furnace with perforations underneath called “tuyeres.” Molten pig iron was poured into the cupola, and hot air was blasted through the tuyeres. The air blown into the iron caused the molten mass to become white hot, forcing impurities, including carbon, to the surface, where they vented as gases mixed with oxygen and burned to keep the iron molten. This process essentially turned the impurities in the iron into fuel without manually feeding the furnace. Kelly initially called his idea “air-boiling,” but the innovation came to be known as “Kelly’s pneumatic process.”

In 1856, Kelly discovered that Sir Henry Bessemer had patented a similar process in Britain and was trying for the American patent. Kelly managed to file a priority claim to the patent office and successfully superseded Bessemer’s claim. In 1863, the Kelly Pneumatic Process Company was organized, but Kelly

did not receive significant remuneration for his invention until the patent was extended in 1871. He retired to Louisville, Kentucky, where he died on February 11, 1888.

Kier, Samuel (1813–1874)

Inventor and businessman Samuel Kier developed the early American petroleum industry in the 1850s. He was the first to refine crude oil into usable lamp oil.

Although Samuel Kier moved to Pennsylvania at the age of 21, he was born in Saltsburg. His first business endeavor, which he undertook with James Buchanan, who would eventually become the 15th president of the United States, was in canal boats. Kier and Buchanan's company transported canal boats between Philadelphia and Pittsburgh.

In 1847, Samuel and his father, Thomas, went into the business of salt refining. Collecting salt from salt water had a major adverse side effect: oil would get into the salt wells and dirty the salt. Initially, this oil was dumped into the Pennsylvania canal. Kier then determined to do something with the waste oil, particularly after a group of Tarentum residents discovered its ability to produce light. They did so by throwing a burning branch into the stained canal, where, much to their surprise, the oil caught fire.

In 1848, Samuel's doctor prescribed "American Medicinal Oil" to his wife, who had been diagnosed with tuberculosis. The medicine struck Samuel as very familiar, and he eventually realized that it was strikingly similar to the oil that his salt refining company was dumping

into the Pennsylvania canal. Seeing that this was the case, by packaging the oil into small bottles and heavily marketing the product as a natural remedy, Samuel Kier was able to profit from the previously wasted oil.

Samuel Kier next began explore the other possibilities in oil. He went to professor James C. Booth, a chemist in the Pennsylvania region, who analyzed the sample and recommended that Kier distill the oil. Booth provided Kier with plans to build a small still for this. In collaboration with industrialist John T. Kirkpatrick, Kier built the still on Seventh Avenue in Pittsburgh. It consisted of a small kettle that could produce a barrel of distilled crude oil. After several failed attempts, Samuel was able to streamline his process and become more efficient. Eventually he produced an oil that could be used for lighting. He called the product "carbon oil."

In a time when it was difficult to find cheap and reliable sources of light, Kier's carbon oil changed the game. Kier invented a lamp that could resourcefully burn his carbon oil without producing an obnoxious amount of smoke. These lamps were the most efficient available, capable of producing a very bright light source, particularly compared to candles and whale oil lamps. Samuel Kier never bothered to patent his refining process, allowing others to make improvements to his procedures. This would eventually pave the way for the modern petroleum refining.

George Bissell saw opportunity in what Samuel Kier had accomplished and decided to form the Pennsylvania Rock Oil Company. Edwin Drake became the general manager behind James Townsend's business of providing oil to the company. With some help, Drake began drilling for oil in Titusville. He met up with the blacksmith who produced tools for Samuel Kier and continued his search for more sources of "rock oil." Eventually, Drake succeeded in his quest and was responsible for finding an oil source in Pennsylvania capable of filling nearly 3 million barrels. The petroleum refining business in America had begun.

Kinematoscope

A 19th-century machine that displayed a series of still photographs in rapid succession in chronological order, making the object in the photos appear to be moving, the Kinematoscope was different from other devices of the time because it was not a projector; one person at a time viewed the photographs, and the photos displayed were stereoscopic.

Coleman Sellers II (1827–1907) was an engineer and the inventor of the Kinematoscope. He held several patents. His inventions were known for their simplicity and efficiency.

Illustrated engineering books of the time did not clearly depict how machines worked. Magazine advertisements for machinery were not clear either. The drawings of moving parts were confusing. Sellers studied photography to find a way to show precisely how machine components moved.

The Kinematoscope required a series of stereoscopic photographs. A stereoscopic image is created when two photographs are taken of the same object from slightly different angles. When the two offset two-dimensional photos are shown together, the individual viewing the images perceives the illusion of depth.

The illusion of movement was created based on the principle of persistence of vision. It refers to the rapid viewing of multiple still images, resulting in the images blending together to give the illusion of motion.

The first photograph in the series displayed in the Kinematoscope showed the object at rest. The object would be moved slightly, and another photo was taken. The object was moved slightly again and another photo taken. This continued until the cycle of motion was complete. When the series of photographs was displayed in the Kinematoscope, the object would

appear to have depth and to be moving. Subjects of these photo series included a machine wheel turning and a boy hammering a nail.

The Kinematoscope consisted of a cabinet that held an eyepiece to view the photographs, a shield to keep light out of the eyepiece, stereoscopic prisms to get the stereoscopic effect, and a rotating cylinder case that held the photographs. Stereoscopic prints were attached to the cylinder horizontally. Turning the cylinder rotated the photos in “rolodex,” or rolling index-style, presentation before the viewing lenses. The eyepiece and shield were on the top of the cabinet; a knob to turn the cylinder of photos was on the side. The prisms and cylinder of photos were inside the cabinet.

Sellers titled his patent application “Exhibiting Stereoscopic Pictures of Moving Objects” and received the patent in 1861. He advanced the study of pictures of motion and photography a step closer to the motion picture technology developed later that century.

Knight, Margaret (1838–1914)

American inventor Margaret Knight was known as the “Lady Edison” for conceiving and improving more than 50 inventions and receiving about 27 patents on some of them. One of the inventions she is most known for is a machine for creating flat-bottomed grocery bags. The flat-bottomed paper bag has been in continuous use since its creation in 1868.

In 1838, Knight was born in York, Maine, to her parents James Knight and Hannah Teal. At the age of 12, her father died. At the same age, she aided her family by working at a textile mill. While there, she witnessed a worker injured by a steel-tipped object released from a mechanical loom shuttle. From this observation, Knight had the idea for a way to prevent this type of accident, creating a cover for the shuttle while it is in use. Her new invention was successful, stopping a projectile from shooting out of the shuttle. But because she was only 12 years old, Knight lacked knowledge of patents, so her invention, widely used in other mills, never resulted in profit.

By 1868, Knight went to Springfield, Massachusetts, to work at the Columbia Paper Bag Company. During this time, bags used at stores were flat, with an envelope opening. While working at this factory, Knight had the idea to create a bag that would be more useful. The new bag would have a flat bottom instead of being flat throughout. Such a flat bottom also benefited companies that wished to advertise the products in the bags since the bags could stand up.

For Knight's new invention to be widely produced, a machine was needed that could both fold and glue the bottoms of the bags. After experimenting with and altering the machine that she used at work, Knight created an iron machine that created flat-bottomed bags consistently. She took her invention to Boston, where she could improve upon it and patent her idea. During this time, another inventor, Charles F. Annan, stole her idea and attempted to patent it. Knight witnessed this and contested Annan in court. In 1871, Knight won the lawsuit; thus, her new invention was patented under her name. Later, she opened her Eastern Paper Bag Company in Massachusetts.

Knight's invention of the flat-bottomed paper bag has survived since the 19th century and is still in use at many stores. This was not Knight's only patented invention. She had many other patents, including ones for lid-removing pliers, a shoe-cutting machine, and a dress and skirt shield; thus, she was nicknamed "Lady Edison." Knight died at the age of 76 on October 12, 1914, due to pneumonia.

Lady Stitchers' Union

The Lady Stitchers' Union formed in Lynn, Massachusetts, in 1883 to protest working conditions and wages, and by 1886, it had organized almost 3,000 women, representing over two-thirds of the female workforce in the area. Recognized as an assembly by the national Knights of Labor, this union was also known as the Daughters of Labor. Just as the men of the Journeymen Cordwainers' Society had refused to admit women as members, the Lady Stitchers' Union restricted membership to women who worked as shoe stitchers instead of seeking a broad base of women engaged in all trades. As a body, the Lady Stitchers' Union could provide representation for workers to the state board of arbitration, which was responsible for settling disagreements between workers and factory owners.

With the dissolution of the Knights of Labor, many stitchers were later recruited into a new organization that emerged in the 1890s, the Boot and Shoe Workers Union. Thus, women in the Lady Stitchers' Union both stood up for their rights as workers and resisted the gendered double standard of many labor unions at a time when American society had difficulty recognizing women as waged laborers.

Lawn Mower, Reel-Type

A reel-type lawn mower has blades that spin north to south in a scissoring action. This type of mower, often called a “push mower,” usually has three to seven rotating blades. Amariah Hills of Hockanum, Connecticut, received the patent for the reel-type lawn mower in 1868.

Hills was the first person in the United States to receive the patent, even though in 1830, inventor Edwin Beard Budding, an engineer from Gloucestershire, England, had also designed a reel-type lawn mower. His mower worked by rotating a blade around the horizontal axis of the cylindrical shape of the mower; it was also known as the cylinder mower. It used two large cast-iron rollers that gave the traction needed to rotate the blades between the rollers. When Hills applied for the first American patent for the reel-type lawn mower, he opened up the cylinder housing. He also improved on it by allowing for height adjustment and improving how the handle attached to the mower’s frame. His mower was human powered, lightweight, and easy to use.

Amariah Hills began his designs for the reel-type lawn mower in 1861 and began manufacturing the machine in 1867 at the Curtis silver plate factory in Glastonbury, Connecticut. Hills sold the patents to Caleb Talcott, who created the company Archimedean Lawn Mower Co. in 1871. The name “Archimedean” came from how the reel-type lawn mower’s spiral cutter looked like an Archimedean screw. The lawn mower was widely accepted, and the “Charter Oak” model had an advertisement that called it “the most beautiful and perfect lawn mower in the world.” The reel mower does not cut very tall grass that well, but once a patch of grass is cut to a lower height, it can easily manage the height of the grass as well as keep the lawn healthy. Indeed, lawn enthusiasts contend

that the reel-type mower creates healthier lawn and creates a more professional, manicured look.

Lennox, David (1855–1947)

David Lennox was an American mechanic, inventor, and businessman and the first to manufacture the riveted steel sheet metal coal furnace. He demonstrated his business skills with the creation of the Lennox Machine Company in 1895, which has evolved to an intercontinental company now known as Lennox International Inc.

Lennox was born in Detroit, Michigan, on April 15, 1855, the first of four children to Martin and Ellen Lennox. In the late 1850s, the family decided to move to Aurora, Illinois. Lennox’s father volunteered in the Civil War and was killed on May 16, 1863. This event greatly affected the family. Lennox was separated from his mother and sent to the Soldiers’ Orphans Home in Springfield, Illinois. Later, he rejoined his family and attended Bryant and Stratton Business College.

Like his father, Lennox was an expert railroad mechanic who quickly became interested in the use of tools and machines. After struggling to support himself financially, he decided to open his own machine shop. His first invention was a staple-cutting machine. The invention was an instant success, and the reputation for his Lennox Machine Shop grew quickly.

One day, a couple by the names of Ernest Bryant and Ezra Smith showed Lennox their plans for a new furnace. The furnace they described used riveted steel instead of cast iron. The quality and safety advantages of such a furnace were enormous. Cast-iron furnaces

were prone to warping over time, leading to cracks and allowing smoke and coal gas to leak into the home. Lennox and the couple solved this problem, and after making a number of modifications to the original design, began the construction of the new furnace, which became such a great success that in 1903 alone, over 1,500 furnaces were produced.

In 1904, Lennox decided to sell his business, the Lennox Furnace Company, to a local group led by D. W. Norris. Lennox continued to manage the company, which employed over 100 people at the time. Today, it is a multinational corporation called Lennox Industries, specializing in climate control products for heating, ventilation, air-conditioning, and refrigeration. The company is traded on the New York Stock Exchange and has a current market cap of over \$6.5 billion.

On February 15, 1947, Lennox died at the age of 91. His revolutionary work, which began with his job as a railroad mechanic and led to creating his own company that manufactured a revolutionary furnace, shows how bright ideas can change the world.

Linotype Machine

The Linotype machine was invented by Ottmar Mergenthaler (1854–1899) in 1883 and revolutionized printing. This "line casting" machine produced an entire line of type in a single piece of lead called a "slug." The machine revolutionized the letterpress printing industry by speeding up the process of typesetting, which previously had required compositors to set individual letters by hand.

Mergenthaler was born in Württemberg, Germany, on May 11, 1854. He trained as a watchmaker's

Linotype machines use a hot metal typesetting system to cast lines of type, rather than typesetting letter by letter. These machines revolutionized printing, particularly in the newspaper business. (Library of Congress)

apprentice and in 1872 immigrated to the United States, where he worked building scientific instruments for his step-cousin August Hahl in Washington, D.C. When Hahl moved his shop to Baltimore, Mergenthaler relocated and eventually became his business partner.

In 1876, Mergenthaler was asked to troubleshoot Charles T. Moore's patented design for a newspaper typewriter that would replace the need to hand-set type. Mergenthaler dedicated himself to working out the mechanics of the system, but after two years of this, it became apparent that the design was flawed.

Undeterred, Mergenthaler designed his own machine that could cast lead type and do typesetting in one operation. He produced an experimental model and in 1883 built a full-size working machine. Like other typesetting machines in use during the 1880s, this one punched letters into a papier-mâché matrix, which was then used to cast type.

Mergenthaler tried a new approach that would do away with the intermediate papier-mâché matrix so that the matrices could be stamped directly onto the metal and cast into type. In 1884, he demonstrated the direct casting band machine to a group of financial backers, and together they formed the National Typographic Company. Justifying (aligning) type was a problem, but Mergenthaler added a space band that would insert space at intervals along the line of type and produce even margins.

In 1885, Mergenthaler formed the Mergenthaler Printing Company and built 12 machines, initially called “blowers” and later named Linotype for the “line of type” they produced. The first machine was sold to the *New York Tribune*, and on July 3, 1886, the first newspaper composed on a Linotype machine went to press.

Trouble with his financial backers led to Mergenthaler’s resignation in 1888, so he launched Ottmar Mergenthaler & Company in Baltimore, where he manufactured parts for Linotype machines. In 1891, both companies merged into Mergenthaler Linotype Company. Within a few years, Mergenthaler fell ill with tuberculosis. In 1894, he moved to New Mexico for recuperation, but his health worsened and he died in 1899.

The patents on the Linotype machine expired in 1911, and competitors such as Intertype quickly entered the profitable market. The Mergenthaler Linotype Company published *The Linotype Bulletin* and mailed it to printers at no cost. The *Bulletin* ran news articles, contests, and help-wanted listings in addition to showcasing the company’s fonts and decorative type elements.

In the mid-1950s, more than 70,000 Linotype machines were in use, but by 1975, hot metal typesetting gave way to phototypesetting systems such as the Linotype CRTronic, until these were edged out by desktop publishing systems in the 1990s.

Margarine

New Yorker Henry Bradley patented a vegetable-based margarine, sometimes called “oleo” or “oleo-margarine,” in 1871. By the beginning of the 20th century, over three dozen American companies were manufacturing the butter substitute. In the mid-20th century, Americans ate more margarine than butter, in part because it was cheaper and in part because manufacturers claimed it was more healthful. Such claims have since been debunked.

While faux butter, or margarine, dates back to the early 1800s, the spread was once made with beef fat. Henry Bradley developed a process that combined cottonseed oil with other vegetable oils and emulsified them into a butter-like spread. The spread became so popular that the butter industry fought back. In 1886, the U.S. Congress passed the Margarine Act that taxed margarine at five times the rate of butter. The act was repealed in 1850.

While margarine is less popular in the early 21st century, it remains a viable commercial product. Observant Jews use margarine as a dairy substitute, as do vegans and the lactose intolerant. Oleo or margarine is often referred to as “nondairy spread.”

Matchbook Matches

A matchbook cover is a small, thin, cardboard paper that covers a pack or strip of matches that is made to be opened and closed like a cover of a book. A person rips a stick out of the book and strikes it once along a black strip to cause the stick to light up with fire. The cover of the matchbook may contain an advertisement, a logo, or artwork.

In 1826, John Walker noticed that a stick that was coated in sulfur accidentally burst into flame when he scraped it on the bottom of his fireplace. Coincidentally, Walker was a chemist, so, with his curiosity, he was the first to invent a friction match. In 1889, this led an attorney named Joshua Pusey to be interested in inventing and holding a patent for the matchbook. After 1894, it grew in popularity. American companies started to add advertisements to matchbooks. They were popular during this time because they were small, portable, easy to use, affordable, safe, and allowed a person to light one small stick at a time.

Matchbook matches still exist and are readily available. One can find them in places like hotels, restaurants, and gas stations. Matchbook matches can be custom made for weddings and other special events.

Matzeliger, Jan Ernst (1852–1889)

Jan Ernst Matzeliger was an inventor who devoted his life to the design, patent, and manufacture of the first shoe lasting machine. The machine completely revolutionized the shoe industry, increasing the manufacturing output capacity of shoes by more than 10 times and making shoes more affordable even for the average person.

Matzeliger was born on September 15, 1852, in Paramaribo, Republic of Suriname. His father was a

Dutch engineer, and his mother was Surinamese. When he was 10 years old, Matzeliger worked in machine shops that his father supervised. When he was 19, he left his family and decided to travel the world, and in 1873, he settled in Philadelphia. Because of his dark skin, Matzeliger struggled to find a sustainable job and decided to resettle in Massachusetts and seek work in the shoe industry.

At the time, the shoe industry was still in its infancy. Cobblers made each shoe almost entirely by hand, through a very delicate and tedious process. Molds of customers' feet had to be made with wood or stone, from which the shoes were sized and shaped. Attaching the body of the shoe to its sole was done entirely by hand. Matzeliger realized that there was a need for improvement and set out to find a solution. He knew that to increase output capacity, much of the manufacturing process had to be automated by machines.

Matzeliger came up with many designs, and after years of development, he applied for a patent on a "lasting machine." On March 20, 1883, Matzeliger received patent number 274,207 for his machine. His machine produced from 150 to 700 pairs of shoes per day, compared to the 50 pairs of a typical skilled worker. Because of the overwhelming demand for the machine, the Consolidated Lasting Machine Company was formed, which began producing shoes in massive quantities.

Unfortunately, Matzeliger did not see the full success of his invention, dying on August 24, 1889, at the age of 36. His early death had been caused by a quickly developing tuberculosis as he spent countless hours working on his inventions, not eating for long periods. Yet, even after his death, his work continued to disrupt the shoe industry. A merger of the Consolidated Lasting Machine Company and a few others led to the creation of a new company called the United Shoe Machinery Company. USMC continued to revolutionize shoe manufacturing and the shoe industry itself. With over 800 new and improved shoe machines and more than 9,000 patented inventions, the USMC became one of the first three international companies ever formed to become a worldwide powerhouse.

Maxim, Hudson (1853–1927)

Hudson Maxim was an American chemist who invented several different explosives, including smokeless gunpowder, a propellant used in firearms and artillery that produces small amounts of smoke when fired. The original form of gunpowder, called black powder, produced a significant amount of smoke. In his risky experimental career, he lost his left hand in a mercury fulminate explosion in 1912. During World War I, Maxim wrote a book titled *Defenseless America*, in which he pointed out the American defense system’s weakness against foreign aggressors and the vulnerability of the country to attacks.

In the mid-1800s, gun technology and warfare were changing. Smokeless gunpowder transformed the efficiency and methods used in firearms. Maxim is comparable to Steve Jobs in today’s day and age with his innovative thoughts and remarkable ability to bring to life what no one knew they needed.

Black powder had been the world’s choice of explosive and gun propellant for thousands of years. It was made by mixing sulfur, charcoal, and potassium nitrate, which was often mined on distant islands with large bird populations, or from caves populated by bats; their droppings were rich in the needed ingredients. Very few changes were made to black powder’s mixture until the strain of the wars, and the thirst for ingenuity began.

Black powder was an unreliable resource and had several problems in battle. Its use would quickly block the battlefield with thick smoke, making it difficult for soldiers to see. One of the main issues was that if the powder became wet, it would not burn, leaving

soldiers defenseless. Without smokeless gun powder, military snipers would give up their positions before even taking a shot, making all following shots dangerous. And, when the trigger was pulled, smoke would surround the gun from the time the shot left the barrel. Not only was this not ideal for battle, it wasn’t hunter friendly either. The time delay allowed animals to disappear before the next shot.

Guncotton was the main ingredient in smokeless powder. The mixture created something with more than triple the amount of power than regular gunpowder, and it burned with little to no smoke. Without Hudson Maxim’s invention of smokeless powder, there would have been a massive innovation gap between the eras. Maxim was a pioneer of his time and contributed greatly to the success of this nation.

Metal Detector

The metal detector was first invented by Alexander Graham Bell during one of the most disastrous moments in U.S. history. This invention was possible because Bell had already invented the telephone several years earlier, and some of the concepts, ideas, and knowledge were transferred to the first metal detector. Bell invented it to detect the bullets inside

President James A. Garfield's body after he was shot in an assassination. Although it failed to save the president, the idea of detecting the existence of metal was passed on to many other applications. Today, metal detectors can be found in every industry from amateur treasure hunting to security systems in all industries.

The idea behind the first metal detector is simple. Any magnetic field is disrupted when there is a metallic object inside the field. If there is a way to capture that moment of disruption, the approximate location of the object can be pinpointed by reducing the area or strength of the magnetic field. This is achieved by using an electrically induced magnetic field that can be adjusted by adding or removing the number of coils. The easiest way to capture the moment is to use telephone technology, which captures sounds from electric current. By combining a telephone receiver and electrically induced magnet, the first metal detector was invented.

One major requirement for the first metal detector to work was that there could be no unnecessary metallic object near the target, because it would interfere with the magnetic field and create false positives. Most important, there should be no large metallic sheets in the background, which was the main reason that the detector might fail.

After a few adjustments, Bell's invention managed to detect the bullets in the clenched hand, pinpoint a bullet lodged in the back of an old veteran, and find a fresh bullet shot into some meat he had bought at butcher shop. However, the detector failed to pinpoint the bullet inside the president's body several times. One possibility was that the springs of the mattress he was on were made of metal. Due to skeptical doctors and the president's weak condition, Bell was barred from performing another test, and unfortunately, the president passed away from the bullet wound.

While the first metal detector failed to save the life of President Garfield, its improved version, a telephone probe, saved many lives in many wars, including World War I, before x-ray detectors were widely used. However, the role of metal detectors has not diminished. Modern metal detectors are more advanced and widely used in clearing land mines, searching for lost or

antique valuables, and for security purposes at airports and other large gathering events.

Metal Electrode Weld

The metal electrode was suggested by Charles Coffin as a filler to maintain the original structure of metals during the process of shielded arc welding, itself a welding technique patented by Coffin in 1889. Coffin's invention rectified the vulnerability of forge welding, which destroys the original shape of the metals. Soon after it was invented, shield arc welding played a big role in both World Wars in terms of shipbuilding.

Welding is a technology that was discovered independently and repeatedly by several communities throughout history. Before arc welding, forge welding was the main industrial practice. In forge welding, two pieces of metal are held together and heated to soften them so they can be merged by various methods, mainly hammering. Forge welding destroys the original metals, while shielded arc welding does not. It uses the electric arc invented by Sir Humphrey Davy of England in 1801. The electric arc is created by placing together two terminals of a high-voltage circuit, producing a bright light and emitting huge amounts of heat. Coffin used three pieces of metal to perform arc welding, placing all three of their edges and heating them with the arc. Two metals were joined by filling the gap with melted metal from a rod—the electrode core with carbon in it. It melts and becomes the filler metal.

Just as welding was discovered separately by different communities, arc welding was also discovered by another person around the same time. Nicholas G. Slavianoff invented similar shielded arc welding in England, applying for a patent on the “Electrical Casting of Metals.” However, his process was very similar to Coffin’s; the only difference was in the type of electrode. Slavianoff used bare metal while others used carbon electrodes.

The first American arc welding machine was imported from Germany in 1907. It had a 200-amp, 60-volt generator. By 1912, four companies offered arc welding machines in the United States, which proved useful during World War I. When the United States entered the war, it had a problem shipping supplies and manpower across the Atlantic Ocean and needed to build new ships quickly. Britain was using arc welding after the gas supply for gas welding ran out, so the States decided to use it build their new ships. Since then, arc welding has become a standard for building U.S. ships and was responsible for most of the ships built for World War II as well.

Today, arc welding is used around the world, and countless innovations were made to the original technique invented separately by Coffin and Slavianoff.

Metal Windmill

The first metal windmill, the “iron turbine,” was patented by J. S. Risdon in 1872 after being manufactured by the firm of Mast, Foos and Company at Springfield, Ohio. This was the first time that

windmills were made purely of metal, and the slow transition from wooden to metal windmills began. However, this took such a long time that wooden windmills were still used 60 years later in 1940.

Before World War I, wooden windmills were more popular than metal ones. When the British first settled in North America, they brought their windmill technology with them. During the colonial era, windmills were mainly used to grind grain. After the American Revolutionary War and various expansion westward, the purpose of windmills changed. By the 1870s, they were used mainly to pump water. However, they were still made of wood. The only metal parts were the screws and bolts.

After being patented in 1872, the iron turbine entered the market in 1876. Risdon claimed that it was the most powerful windmill at the time when compared to others of the same diameter. He had replaced straight blades with buckets on the solid wheel of the mill. There was another metal windmill that entered the market at the same time: the Leffel Iron Wind Engine. However, it was not completely made with metal; only its wheel and head were. The rest was still composed of wood. Metal windmill production increased in the United States starting from the 1890s, with the help of cheap steel prices.

In the 1880s, another notable metal windmill appeared. The Iron Duke entered the market with the slogan that it would not warp, shrink, swell, split, or decay, and its slats would not blow away in any storm. However, users were skeptical of metal windmills mainly because they were harder to repair. Farmers knew how to fix wooden windmills with nails and bolts. Hence, they were unwilling to switch over to the new windmills. Another reason that they wanted to continue using wooden windmills was because metal ones were weaker. Because of the weight of metal, they required more wind power to operate at the same level as wooden windmills. Manufacturers of metal windmills switched to lighter metal to quell the complaints. In fact, the metals they now used were lighter than necessary. Among customers, those from the Southwest region of the United States were the last to switch to metal windmills, believing that wooden lasted longer than their metal counterparts.

This 1880 engraving of the iron turbine wind engine, the first metal windmill, suggests the apparatus's importance to Western farming. Technically wind pumps, these machines pumped water to the surface, supplying crop irrigation and water for cattle. (Archive Photos/Getty Images)

Windmill technology has evolved by leaps and bounds since the 1900s, with countless innovations in design by numerous inventors around the world. Nowadays, windmills' purpose has changed again; they are mainly associated with generating environmentally friendly energy. Although the metal windmills invented by Risdon and others are no longer widely used, the current version of windmills might never have been possible without those durable metal windmills.

Military Technology (Post-Civil War through World War I)

Military technology has constantly changed as wars have been fought. Improvements in technology and new ideas are aggressively pushed by every side at war to try to get the upper hand in battle. While military technology might arise around an immediate opportunity for advantage in battle, it can sometimes evolve into something that can help (or maybe hinder) civilian society. Most technology developed for military use consists of weapons, though some does not

necessarily have military application. Some technologies that were created and improved on through the Civil War and World War I still impact our lives today.

The Civil War helped create and improve technologies that would forever change how wars were fought. Civil War technology would not only have a drastic effect on the war's outcome but would also change future military strategy. Inventions and improvements during the Civil War included the rifle, repeaters, submarines, the railroad, and the telegraph.

Prior to the Civil War, soldiers had fought mainly with muskets, which only carried a single shot and took a long time to reload. The range of typical muskets was about 250 yards; they were much more effective and accurate at a closer range, which meant that armies usually had to approach each other relatively closely. While some rifles used in wars had a much better range, they were not as effective, because bullets were roughly the same size as rifle barrels and had to be hammered in with mallets. This changed in 1848, when a French Army officer named Claude Minié invented a cone-shaped lead bullet that would later be known as a “minié ball.” These bullets could be loaded much more quickly and had a farther firing distance. They also caused much more damaging wounds, which medical care at the time was ill prepared to handle. Wars would no longer be fought in close quarters, and even the soldiers in the distance had to find a means of protecting themselves. They did so by building forts or trenches.

The minié bullets allowed for easier reloading of rifles, but they still could only load one bullet at a time. This led to the creation of “repeater” rifles or weapons. The most famous repeater of the Civil War was the Spencer carbine. It was a much shorter and lighter version of the standard-issue muzzle-loading rifled musket. It was capable of shooting up to seven rounds in 30 seconds before having to be reloaded. The Henry rifle was another repeater that was introduced just before the start of the Civil War. Unlike the Spencer carbine, the Henry rifle had much less energy but could hold 16 rounds.

While the battles of the Civil War were mostly fought on land, there were important innovations that would change how wars would be fought on water and in the air. The Civil War saw a more aggressive

implementation of the use of submarines and balloons during warfare. Submarines had existed long before the Civil War, but it was the Confederate CSS *Hunley* that would go down in history as the first submarine to engage and sink an enemy vessel. The *Hunley* submarine was a 40-foot-long, 4-foot-wide metal tube operated by only an eight-man crew. The Union had a blockade that covered 3,500 miles of the Atlantic and Gulf Coast line that was preventing the Confederacy from trading and getting supplies to its soldiers. The coasts were guarded by the Union with the use of ironclad ships. Ironclad and steel armor-plated ships were implemented during the Civil War instead of wooden ships, which were vulnerable to explosions and incendiary fire. The Confederacy retaliated with the sinking of the *Housatonic*, which was one of the Union's blockade ships off the coast of Charleston. While the *Hunley* successfully sank an enemy vessel, it sank itself in the process.

While there is also evidence of balloons being used in battle as early as 1794, during the Civil War, they were used to spy on the enemy and to send information back to base via telegraph. One improvement to accomplish this was created by Union Chief Aeronaut Thaddeus Lowe: mobile hydrogen gas generators. They allowed soldiers to fill up balloons almost anywhere they needed to. This tactic by Union soldiers caused Confederate soldiers to come up with ways of disguising their troop numbers and movements by devising camouflage and the first campfire “blackouts.” These tactics would also be used later on in the World Wars.

While advancements in weapons changed the outcomes and tactics of battles, innovations like the railroad and the telegraph would cause much more impactful change to the entire world. The railroads had a massive impact on the outcome of the war by helping move large quantities of soldiers and supplies. Much like in all of the other technological advances during the Civil War, the Union had an advantage in obtaining and using them due to the majority of factories being in the North. Railroads in the North consisted of standard-gauge tracks that allowed trains to run on any of them, while in the South, there was no standard for tracks and thus, people had to switch trains constantly—which was highly inefficient.

The invention of the telegraph was another technology that gave the Union a major advantage over the Confederacy. With the telegraph, the Union was able to send and receive messages from the battlefield in real time, allowing them to adjust and strategize in a timely manner. This led to the establishment of the U.S. Military Telegraph Corps by the Union Army. Just a year after it was established in 1861, the Corps had run 4,000 miles of telegraph wire and trained 1,300 operators. Innovations like the railroad and telegraph are examples of military technologies that have evolved into other forms that still have an impact on us today.

World War I, like the Civil War, was the impetus for many technological advances that were initially implemented for war but would have an impact on civilian life as well. Some of the more impactful innovations to come from World War I are technologies like machine guns, tanks, and mobile x-ray machines.

As in the Civil War, the need for more rapid firepower was the focus during World War I. This resulted in the development of machine guns. The first machine guns were very primitive. Heavy and not suited for advancing armies, they were mostly used in groups to hold on to a defensive position. Even though they would regularly overheat or jam, the firepower they produced was like nothing ever seen before.

With just one machine gun capable of mowing down dozens of soldiers in a short time, armies had to come up with methods of protecting themselves from the line of fire. The creation of the automobile in the 1900s helped create a great military technology. Begin with a vehicle powered by a small combustion engine and heavily armor plated to take on enemy fire, add some firepower and replace the wheels with armored tread, and you have a tank. Tanks were initially very primitive as well, but they were much more efficient before the end of the war.

Sadly, the use of machine guns and tanks as well as other weapons caused soldiers to suffer gruesome wounds. This created a need to improve medical technology in the field as well. Prior to the Great War, x-ray machines were very large and too bulky to have out on the battlefield. Marie Curie helped create mobile x-ray stations for the French military soon after the war broke out. The machines were installed

in small trucks or cars that were accompanied with smaller surgical stations at the front. Before the end of the war, there were 18 “radiologic cars” or, as some called them, “little Curies” in operation.

War is the cause of great death and destruction, but ironically, it has also been the cause of many great, innovative technologies. Through the use of science and technology, humanity has brought great harm upon itself with its wartime innovations, but it has also helped society advance.

Mining Sulfur Fluidically. See Frisch Process

Motion Picture Camera

The motion picture camera, also called the film camera or cine-camera, takes photographs in rapid sequence. Each image it takes is called a “frame.” When frames are played back in sequence and at a

specific speed, they create the illusion of motion. The invention of the motion picture camera revolutionized the film industry in America. From the advancements made by the kinetoscope and the kinetograph, cameras and video recorders evolved from the basic standard set by Thomas Edison's (1874–1931) invention to the digital cameras of 21st-century movie making. The motion picture camera made it possible for Americans to shape culture with entertainment, rally troops with war propaganda, and more.

The first design of the motion picture camera was the kinetoscope, a large box used for the viewing of motion films. It involved a cylinder coated with collodion, an agent that was used in early photo development (1851). However, collodion was too coarse to use on the cylinder and failed to provide a clear picture. The very first motion picture camera was patented in 1876, and many major variations of the invention were devised in England, France, and Britain. Before the invention of the motion picture camera, Edison created the kinetoscope. It was the sister invention to the movie camera and was significant for the development of mechanisms used in the motion picture camera.

The Edison motion picture viewing device, or kinetoscope, was first created sometime between 1889 and 1892 by Thomas Edison and William Kennedy-Laurie Dickson. It was the first commercially successful moving image invention that used a patented electric motor-powered sprocket technology not used in any other variation. The invention was inspired by a lecture from Eadweard Muybridge, who used a zoopraxiscope (created in 1879) to simulate the motion of animals and create the illusion of movement. Although Edison provided the concept for the machine, he relied heavily on Dickson's knowledge of photography to help the idea come to fruition. Dickson was given control of the experimentation needed to develop the camera and eventually developed a kinetographic camera in 1891 with the Edison Lab team.

Celluloid sheets, invented by George Eastman in 1889, were next used on the cylinder to provide a much cleaner recorded image. The first motion picture ever recorded in the United States was called *Monkeyshines, No. 1*. The short film was of one of Thomas Edison's employees, taken to test the effectiveness of the cylinder format in the kinetoscope. The cylinder format was

later changed around 1890 to a film strip format after Edison traveled to Europe and obtained new concepts for the invention, such as flexible, perforated film that could be carried along smoothly by sprockets.

The kinetograph, or motion picture camera, was developed and patented by Edison in 1891 shortly after the kinetoscope and is the sister invention to the motion picture viewing device. The kinetograph took video by using an intermittent mechanism composed of an electrically motorized perforated-film-and-sprocket system that synched the film and the shutter so that the camera would stop each frame before the lens long enough for the shutter to open and expose the film. In comparison to other motion picture cameras that were invented around the world, Edison's film-and-sprocket system allowed for a faster film frame rate and a smoother recording process without mechanical errors or the cumbersome method of hand-feeding film into the device. The film taken with the kinetograph could then be played back at some speed to create the illusion of movement. It could shoot up to 50 feet of film at 40 to 46 frames per second for up to 30 minutes. The kinetograph set the standard for future filming inventions and technology and revolutionized the filming process, helping popularize the film industry in the United States. The perforated-film-and-sprocket system used in the kinetograph is still used in modern motion picture cameras because many film producers prefer a more traditional approach to filming, and it provides a greater depth of field and larger exposure latitude. Many film producers continue to prefer film cameras and use the depth of field to grab the audience's attention or use the extended exposure latitude to darken details not needed in movie shots.

In 1911, Bell and Howell Company introduced the first metal movie picture camera, and in 1932, the Mitchell Technicolor camera allowed movies to be shot in color using three strips of film filtered to capture purple, green, and red. In 1923, Eastman Kodak introduced 16-mm film stock as a low-cost alternative to 35-mm film stock. Thus, the amateur movie-making market was born. By the 1950s, middle-class American households generally owned movie cameras with which they filmed a variety of "home movies," generally commemorating birthdays and holidays.

In the 21st century, digital movie cameras have come to dominate the movie-making industry and movie camera market. In fact, digital movie cameras for the mass consumer market have made low-cost, independent movie-making possible, opening new fields of movie production.

National Consumers League

The National Consumers League (NCL) was founded in 1891 as part of the Progressive Era's reform impulse. In 1891, the Consumer's League took form in New York, Massachusetts, Pennsylvania, and Illinois. In 1899, the leagues united to become the NCL, adopting the motto "Investigate, agitate and legislate."

Florence Kelley served as president of the NCL from 1899 to 1932. She graduated from Cornell in 1882 and then went on to study law and government at the

University of Zurich. Kelley became a socialist and married a Russian medical student. They had three children together before she fled from his abuse and moved to Hull House in Chicago. While raising her three children alone, Kelley took night classes at Northwestern Law School and earned her degree. In 1895 Kelley's lifelong battle with the courts began when she persuaded the Illinois state government to help fund her research on industrial working conditions in Chicago.

In 1908, the NCL prepared the brief used by Louis Brandeis, a lawyer in the *Muller v. Oregon* case, in which the U.S. Supreme Court enforced a state law for the maximum of work hours for women. The NCL drafted the nation's first minimum wage law, which was enacted in Massachusetts in 1912 and spread to 12 other states within a few years. During the early 1900s, the NCL participated in promoting the Meat Inspection Act of 1904 and the Pure Food and Drug Act of 1906. Understanding the pressures of competition in the workforce, the NCL placed responsibility on not only the employer but also the consumer.

As an early attempt to encourage employers to volunteer information on working conditions, the NCL implemented a "white list" and "white label." Though the word "white" was meant as a contrast to the term "blacklist," the action ultimately repelled African Americans from joining the movement. However, the label was successful in recruiting middle-class women and educating them on labor practices. Jewish women also played a role in the NCL and were significantly more likely to support women in the workforce and activism.

During the Progressive Era, the NCL gained popularity due to the organization's demand for ethical consumption. Upon Kelley's death, Lucy Randolph Mason directed the NCL, followed by Mary Dublin (Keyserling) from 1938 to 1940. Eleanor Roosevelt served as the vice president of the NCL and testified on behalf of the organization on numerous occasions. During this time, the NCL was most focused on passing the 1938 federal Fair Labor Standards Act. This important legislation addressed issues that included child labor, minimum wage, restrictions on hours worked, and industrial homework. In addition, the NCL also advocated for national health insurance,

improved food and drug safety laws and federal pesticide monitoring, social security legislation (namely for the elderly and the disabled), and unemployment insurance.

In 1943, Elizabeth Magee directed the NCL; she moved the organization's office to Cleveland, Ohio, her hometown. Magee placed the group's emphasis on equal pay for equal work for women, extension of fair labor laws to migratory workers, guaranteed compensation for workplace accidents, and disability coverage under social security. At the end of Magee's term as director, in the fall of 1958, the NCL office moved back to the East Coast and to Washington, D.C.

Vera Waltman Mayer and Sarah Newman led the NCL into and throughout the 1960s. During this time, the organization focused on consumer protection, prioritizing issues such as health assistance for migratory workers, Medicare and Medicaid, wholesome meat and poultry, truth-in-packaging legislation, food additive and coloring testing, and worker safety in atomic industries.

During the 1970s and 1980s, the executive director, Sandra Willett Jackson, created the Assertive Consumer project in an attempt to increase consumer education. During this period, influential figures such as Esther Peterson served as vice presidents of the NCL. Peterson was a renowned labor and consumer leader and regularly testified on behalf of the NCL. She went on to become head of the White House Office of Consumer Affairs under President Jimmy Carter. Before that, Peterson also served as consumer advisor to Presidents John F. Kennedy and Lyndon Johnson. The NCL established the Alliance Against Fraud in Telemarketing and the Child Labor Coalition in the 1980s. Today, the NCL advocates for the safe use of medication, better working conditions for migrant farmworker families and teen workers, improved product safety, and accurate food and beverage product labeling.

National Institutes of Health (NIH)

Operating and conducting research on its main campus in Bethesda, Maryland, the National Institutes of Health is a U.S. government organization that calls attention to and supports biomedical and health-related studies. The agency is also a part of the U.S. Department of Health and Human Services and is known for its significant findings and research seeking to discover more ways to save lives each day. The NIH has over two dozen branches or elements called Centers and Institutes.

While the National Institutes of Health essentially endeavors to strengthen health, it has a variety of goals. It seeks to innovate and develop resources to prevent the spread of illness worldwide and to raise the country's welfare. In all it does, it relies on the principles of science.

In the late 1880s, the NIH was established in a one-room laboratory within the Marine Hospital Service (MHS), offering medical assistance on travelers who arrived on ships and had symptoms of infectious diseases such as yellow fever and cholera. As such occasions became frequent, Congress funded the MHS, later changing its name to Public Health Services and moved it from New York to Massachusetts into a lab at Harvard Medical School. With the Ransdell Act of 1930, the institute was presented with \$750,000 to build two buildings, which later expanded into numerous centers. Finally, the organization became the National Institutes of Health in 1948.

The main office at the NIH establishes regulations and policies, administering affairs throughout the NIH. The director of the national institute is currently Dr. Francis S. Collins, who earned his PhD in physical chemistry from Yale University in 1974. He assumed this post in August 2009. Collins didn't want to focus only on so-called the "big three" diseases AIDS, TB, and malaria. He wanted more research on other fatal but nontransmissible ailments such as cancer, heart disease, and diabetes. The NIH secured additional funding from the private sector, including from the Bill & Melinda Gates Foundation and the Wellcome Trust, a global charity based in London.

Investing over \$32 billion in research each year, the NIH awards grants to more than 2,500 institutions

such as medical schools and universities and well as studies around the globe.

Niagara Falls Power Plant

The Niagara Falls power plant began the world's electrical age. It was the first plant to supply massive amounts of electrical power to consumers at reasonable prices, and it spurred the electrical appliance, aluminum, and electrochemical industries. The power of waterfalls remains preeminent in electrical generation throughout the world.

The Niagara Falls have an almost unbelievable average flow of 100,000 cubic feet per second, with a

The Edward D. Adams Power Plant at Niagara Falls, New York, was the first large-scale alternating current-generating plant in the world. Built in 1895, the plant could generate 50,000 horsepower in electricity. (Library of Congress)

peak of 225,000 cubic feet per second. There is a peak period of flow from April to November. There is even a daily variation in the flow, with the peak flow at 9 a.m. and the lowest flow at 9 p.m. German electrical engineer Sir Werner von Siemens estimated in 1888 that “the amount of water falling over Niagara is equal to 100,000,000 tons of coal an hour.” Sir Siemens calculated that “if steam boilers could be erected vast enough to exhaust daily the whole coal output of the earth, the steam generated would barely suffice to pump back again the water flowing over Niagara Falls.”

A battle for the Niagara power plant contract went on between J. P. Morgan and Thomas Edison’s direct current (DC) system versus George Westinghouse’s alternating current (AC). A commission was formed in 1890 to explore whether DC or AC power generation should be selected. The long-distance transmission of AC power to cities such as Telluride, Colorado, and Frankfurt, Germany, helped the commission to select AC and the Westinghouse system. Finally, the success of Westinghouse’s “White City” at the 1893 Chicago World’s Fair was the tipping point. In 1893, Westinghouse’s AC system was selected with a contract to build two 5,000-horsepower generators. Although Westinghouse got the largest part of the contract, General Electric also ended up with some lucrative contracts for transformers and transmission lines.

General Electric’s work on the transformers became critical to Niagara’s success. The AC system and transformers allowed for long-distance transmission of power, which a DC system could not achieve. These transformers stepped up the voltage from a generated 2,000 volts to 10,000 volts as well as changing the two-phase current to three phases. The current at 10,000 volts was then transmitted through bare copper cable (on thousands of insulated wooden poles) to Buffalo, New York, 26 miles away. Full transmission would begin in 1896. General Electric transformers then stepped down the voltage to 110 volts for general lighting and 370 volts for Buffalo’s street-railway system. In the end, Westinghouse’s great victory generated vital profits for General Electric as the Panic of 1893 continued until 1896, when General Electric and Westinghouse started to work together for the good of the Niagara project. Morgan also realized that any

further internal competition would cost the overall project and his syndicate money. Niagara was to be the world’s largest engineering project, requiring Morgan to bring in other financiers such as August Belmont, John Astor, and the Vanderbilts as investors. With Thomas Edison bought out, Morgan converted General Electric to AC technology.

The real man behind the Niagara power project was neither Westinghouse nor Edison nor Morgan, but Nikola Tesla. It was Tesla’s patents that supplied the AC power technology. Tesla’s patents had made AC technology the future. The first power came on at Niagara on August 26, 1895. On that August day, Dynamo No. 2 went online, supplying current to the Pittsburgh Reduction Company. The initial power went to the electrochemical plants nearby. Dynamo No. 1 didn’t come on stream until September 30, at which time the directors of Cataract Construction Company and Westinghouse, plus assorted millionaires, came to celebrate. Two important figures were not present—Morgan, who came later in October, and Tesla. As the plaque at the falls would reflect, Westinghouse gave all the credit to Tesla. In total, 13 of Tesla’s patents were used in the creation of the Niagara power plant. Still, the bitterness of the “war of the currents” had created a bias against Tesla in the New York press controlled by Morgan. The *New York Times* found a way to hail the event without mentioning Tesla, while most other papers hailed Tesla as the equal of Edison in the triumph of the falls. It was a great victory for Westinghouse Electric, but Westinghouse spent time at Pittsburgh Reduction Company, further studying the wonders of aluminum smelting rather than celebrating.

One of the great results of the Niagara power station was the rise of the American electrochemical industry. The two biggest customers of Niagara were the Pittsburgh Reduction Company and the Carborundum Company. The Pittsburgh Reduction Company (the future Aluminum Company of America, or ALCOA) contracted for 5,000 of the 15,000 available horsepower. Niagara finally made the production and use of aluminum economically feasible.

Niagara power’s other big customer was the Carborundum Company. Carborundum was an artificial abrasive composed of aluminum oxide. These alumina

crystals were produced by electrochemical processing, as pure aluminum was. Larger, colored alumina crystals found in nature are sapphires and rubies. The fine artificial alumina crystals are extremely hard, making them ideal for grinding and cutting wheels. Within a year, a massive electrochemical industry grew up around Niagara, including plants producing sodium, soda ash, sodium peroxide, and calcium carbide. By 1897, 12,500 of the 13,500 horsepower available for local consumption went to electrochemical plants. Westinghouse enjoyed visiting these plants, since he always had a fascination with metallurgy. The aluminum industry owes a great deal to Westinghouse.

Within a few years, Niagara had become a major production area for steelmaking ferroalloys such as ferrosilicon and ferrochrome. These ferroalloys required power levels for production that were unavailable until the Niagara Falls power plant. The massive amount of workers needed to build the power system and operate the electrochemical plants required a planned worker town of houses, which would be the first in the country to be lighted and heated by electricity.

Industrialist William Love hoped to emulate Westinghouse's industrial utopian town of Wilmerding, Pennsylvania, by creating an industrial utopia for electrochemical workers. The effort resulted in a mile-long town along the wastewater canal known as the Love Canal. The town failed to grow and became the LaSalle area of Niagara. It would become famous for the old toxic electrochemicals that caused a strange "outbreak" of cancer in the 1970s and an example of the costly legal battles created by industrial pollution.

Buffalo, New York, had originally been the reason for the Niagara project. Buffalo received the necessary amount of current to be applied in street arc lights, incandescent lights in homes, and electric motors in factories, as well as used by the Buffalo Railway Company for streetcars. In 1901, the Pan-American Exposition came to Buffalo to show the world the future of electricity. The exposition highlighted electrical appliances that were in use in Buffalo such as sewing machines, home lighting, neon lights, electric elevators, and laundry machines.

Primary Document: Excerpt from Nikola Tesla's Commemoration Address for the Niagara Falls Power Plant (1897)

The power plant at Niagara Falls was designed by Nikola Tesla and George Westinghouse in 1895. The plant represented the final skirmish in the battle between Tesla's Alternating Current and Edison's Direct Current. Tesla gave the commemoration address for the Niagara Falls Power Plant in 1897. The Electrical Review reprinted his speech that same month. The following is an excerpt of that speech.

ON ELECTRICITY

by Nikola Tesla

(The Address On the Occasion of the Commemoration of the Introduction of Niagara Falls Power in Buffalo At the Ellicott Club, January 12, 1897)

Electrical Review, January 27, 1897

. . . I have referred to the merging together of the various sciences or departments of research, and to a certain perception of intimate connection between the manifold and apparently different forces and phenomena. Already we know, chiefly through the efforts of a bold pioneer, that light, radiant heat, electrical and magnetic actions are closely related, not to say identical. The chemist professes that the effects of combination and separation of bodies he observes are due to electrical forces, and the physician and physiologist will tell you that even life's progress is electrical. Thus electrical science has gained a universal meaning, and with right this age can claim the name "Age of Electricity."

I wish much to tell you on this occasion—I may say I actually burn for desire of telling you—what electricity really *is*, but I have very strong reasons, which my coworkers will best appreciate, to follow a precedent established by a great and venerable philosopher, and I shall not dwell on this purely scientific aspect of electricity.

There is another reason for the claim which I have before stated which is even more potent than the former, and that is the immense development in all electrical branches in more recent years and its influence upon other departments of science and industry. To illustrate this influence I only need to refer to the steam or gas engine. For more than half a century the steam engine has served the innumerable wants of man. The work it was called to perform was of such variety and the conditions in each case were so different that, of necessity, a great many types of engines have resulted. In the vast majority of cases the problem put before the engineer was not as it should have been, the broad one of converting the greatest possible amount of heat energy into mechanical power, but it was rather the specific problem of obtaining the mechanical power in such form as to be best suitable for general use. As the reciprocating motion of the piston was not convenient for practical purposes, except in very few instances, the piston was connected to a crank, and thus rotating motions was obtained, which was more suitable and preferable, though it involved numerous disadvantages incident to the crude and wasteful means employed. But until quite recently there were at the disposal of the engineer, for the transformation and transmission of the motion of the piston, no better means than rigid

mechanical connections. The past few years have brought forcibly to the attention of the builder the electric motor, with its ideal features. Here was a mode of transmitting mechanical motion simpler by far, and also much more economical. Had this mode been perfected earlier, there can be no doubt that, of the many different types of engine, the majority would not exist, for just as soon as an engine was coupled with an electric generator a type was produced capable of almost universal use. From this moment on there was no necessity to endeavor to perfect engines of special designs capable of doing special kinds of work. The engineer's task became now to concentrate all his efforts upon one type, to perfect one kind of engine—the best; the universal, the engine of the immediate future; namely, the one which is best suitable for the generation of electricity. The first efforts in this direction gave a strong impetus to the development of the reciprocating high speed engine, and also to the turbine, which latter was a type of engine of very limited practical usefulness, but became, to a certain extent, valuable in connection with the electric generator and motor. Still, even the former engine, though improved in many particulars, is not radically changed, and even now has the same objectionable features and limitations. To do away with these as much as possible, a new type of engine is being perfected in which more favorable conditions for economy are maintained, which expands the working fluid with utmost rapidity and loses little heat on the walls, an engine stripped of all usual regulating mechanism—packings, oilers and other appendages—and forming part of an electric generator; and in this type, I may say, I have implicit faith.

The gas or explosive engine has been likewise profoundly affected by the commercial introduction of electric light and power, particularly in quite recent years. The engineer is turning his energies more and more in this direction, being attracted by the prospect of obtaining a higher thermodynamic efficiency. Much larger engines are now being built, the construction is constantly improved, and a novel type of engine, best suitable for the generation of electricity, is being rapidly evolved.

There are many other lines of manufacture and industry in which the influence of electrical development has been even more powerfully felt. So, for instance, the manufacture of a great variety of articles

of metal, and especially of chemical products. The welding of metals by electricity, though involving a wasteful process, has, nevertheless, been accepted as a legitimate art, while the manufacture of metal sheet, seamless tubes and the like affords promise of much improvement. We are coming gradually, but surely, to the fusion of bodies and reduction of all kinds of ores—even of iron ores—by the use of electricity, and in each of these departments great realizations are probable. Again, the economical conversion of ordinary currents of supply into high-frequency currents opens up new possibilities, such as the combination of the atmospheric nitrogen and the production of its compounds; for instance, ammonia and nitric acid, and their salts, by novel processes.

The high-frequency currents also bring us to the realization of a more economical system of lighting; namely by means of phosphorescent bulbs or tubes, and enable us to produce with these appliances light of practically any candle-power. Following other developments in purely electrical lines, we have all rejoiced in observing the rapid strides made, which, in quite recent years, have been beyond our most sanguine expectations. To enumerate the many advances recorded is a subject for the reviewer, but I can not pass without mentioning the beautiful discoveries of Lenart and Roentgen, particularly the latter, which have found such a powerful response throughout the scientific world that they have made us forget, for a time, the great achievement of Linde in Germany, who has effected the liquefaction of air on an industrial scale by a process of continuous cooling: the discovery of argon by Lord Rayleigh and Professor Ramsay, and the splendid pioneer work of Professor Dewar in the field of low temperature research. The fact that the United States have contributed a very liberal share to this prodigious progress must afford to all of us great satisfaction. While honoring the workers in other countries and all those who, by profession or inclination, are devoting themselves to strictly scientific pursuits, we have particular reasons to mention with gratitude the names of those who have so much contributed to this marvelous development of electrical industry in this country. Bell, who, by his admirable invention enabling us to transmit speech to great distances, has profoundly affected our commercial and social relations, and even our very mode of life; Edison, who, had he not done anything else

beyond his early work in incandescent lighting, would have proved himself one of the greatest benefactors of the age; Westinghouse, the founder of the commercial alternating system; Brush, the great pioneer of arc lighting; Thomson, who gave us the first practical welding machine, and who, with keen sense, contributed very materially to the development of a number of scientific and industrial branches; Weston, who once led the world in dynamo design, and now leads in the construction of electric instruments; Sprague, who, with rare energy, mastered the problem and insured the success of practical electrical railroading; Acheson, Hall, Willson and others, who are creating new and revolutionizing industries here under our very eyes at Niagara. Nor is the work of these gifted men nearly finished at this hour. Much more is still to come, for fortunately, most of them are still full of enthusiasm and vigor. All of these men and many more are untiringly at work investigating new regions and opening up unsuspected and promising fields. Weekly, if not daily, we learn through the journals of a new advance into some unexplored region, where at every step success beckons friendly, and leads the toiler on to hard and harder tasks.

But among all these many departments of research, these many branches of industry, new and old, which are being rapidly expanded, there is one dominating all others in importance—one which is of the greatest significance for the comfort and welfare, not to say for the existence, of mankind, and that is the electrical transmission of power. And in this most important of all fields, gentlemen, long afterwards, when time will have placed the events in their proper perspective, and assigned men to their deserved places, the great event we are commemorating today will stand out as designating a new and glorious epoch in the history of humanity—an epoch grander than that marked by the advent of the steam engine. We have many a monument of past ages: we have the palaces and pyramids, the temples of the Greek and the cathedrals of Christendom. In them is exemplified the power of men, the greatness of nations, the love of art and religious devotion. But that monument at Niagara has something of its own, more in accord with our present thoughts and tendencies. It is a monument worthy of our scientific age, a true monument of enlightenment and of peace. It signifies the subjugation of natural forces to the service of man, the discontinuance of

barbarous methods, the relieving of millions from want and suffering. No matter what we attempt to do, no matter to what fields we turn our efforts, we are dependent on power. Our economists may propose more economical systems of administration and utilization of resources, our legislators may make wiser laws and treaties, it matters little; that kind of help can be only temporary. If we want to reduce poverty and misery, if we want to give to every deserving individual what is needed for a safe existence of an intelligent being, we want to provide more machinery, more power. Power is our mainstay, the primary source of our many-sided energies. With sufficient power at our disposal we can satisfy most of our wants and offer a guaranty for safe and comfortable existence to all, except perhaps to those who are the greatest criminals of all—the voluntarily idle.

But we shall not satisfy ourselves simply with improving steam and explosive engines or inventing new batteries; we have something much better to work for, a greater task to fulfill. We have to evolve means for obtaining energy from stores which are forever inexhaustible, to perfect methods which do not imply consumption and waste of any material whatever. Upon this great possibility, which I have long ago recognized, upon this great problem, the practical solution of which means so much for humanity, I have myself concentrated my efforts since a number of years, and a few happy ideas which came to me have inspired me to attempt the most difficult, and given me strength and courage in adversity. Nearly six years ago my confidence had become strong enough to prompt me to an expression of hope in the ultimate solution of this all dominating problem. I have made progress since, and have passed the stage of mere conviction such as is derived from a diligent study of known facts, conclusions and calculations. I now feel sure that the realization of that idea is not far off. But precisely for this reason I feel impelled to point out here an important fact, which I hope will be remembered. Having examined for a long time the possibilities of the development I refer to, namely, that of the operation of engines on any point of the earth by the energy of the medium, I find that even under the theoretically best conditions such a method of obtaining power can not equal in economy, simplicity and many other

features the present method, involving a conversion of the mechanical energy of running water into electrical energy and the transmission of the latter in the form of currents of very high tension to great distances. Provided, therefore, that we can avail ourselves of currents of sufficiently high tension, a waterfall affords us the most advantageous means of getting power from the sun sufficient for all our wants, and this recognition has impressed me strongly with the future importance of water power, not so much because of its commercial value, though it may be very great, but chiefly because of its bearing upon our safety and welfare. I am glad to say that also in this latter direction my efforts have not been unsuccessful, for I have devised means which will allow us the use in power transmission of electromotive forces much higher than those practicable with ordinary apparatus. In fact, progress in this field has given me fresh hope that I shall see the fulfillment of one of my fondest dreams; namely, the transmission of power from station to station without the employment of any connecting wire. Still, whatever method of transmission be ultimately adopted, nearness to the source of power will remain an important advantage.

Gentlemen, some of the ideas I have expressed may appear to many of you hardly realizable; nevertheless, they are the result of long-continued thought and work. You would judge them more justly if you would have devoted your life to them, as I have done. With ideas it is like with dizzy heights you climb: At first they cause you discomfort and you are anxious to get down, distrustful of your own powers; but soon the remoteness of the turmoil of life and the inspiring influence of the altitude calm your blood; your step gets firm and sure and you begin to look—for dizzier heights. I have attempted to speak to you on "Electricity," its development and influence, but I fear that I have done it much like a boy who tries to draw a likeness with a few straight lines. But I have endeavored to bring out one feature, to speak to you in one strain which I felt sure would find response in the hearts of all of you, the only one worthy of this occasion—the humanitarian. In the great enterprise at Niagara we see not only a bold engineering and commercial feat, but far more, a giant stride in the right direction as indicated both by exact science and philanthropy. Its success is a signal for the utilization of water powers all

over the world, and its influence upon industrial development is incalculable. We must all rejoice in the great achievement and congratulate the intrepid pioneers who have joined their efforts and means to bring it about. It is a pleasure to learn of the friendly attitude of the citizens of Buffalo and of the encouragement given to the enterprise by the Canadian authorities. We shall hope that other cities, like Rochester on this side and Hamilton and Toronto in Canada, will soon follow

Buffalo's lead. This fortunate city herself is to be congratulated. With resources now unequaled, with commercial facilities and advantages such as few cities in the world possess, and with the enthusiasm and progressive spirit of its citizens, it is sure to become one of the greatest industrial centers of the globe.

Office Technology (Pre–World War II)

The second half of the 19th century witnessed a profound transformation in American offices as well as the technologies needed to administer the increasing workload resulting from an increase in population and the advance of American industry. As the country expanded westward, land, railroad, telegraph—and soon telephone—offices required efficient means for creating, organizing, and distributing paperwork as well as tabulating and recording finances and accounts. By the time of the Centennial Exposition held in Philadelphia in 1876, great advances in paper fastening and calculation, among other products, demonstrated how invention and innovation met the pressing needs of the work environment.

George McGill, an inventor born in Lancaster, Ohio, and operating in New York City, patented a brass fastener in 1866 and a device to cut a hole in the paper to accommodate the fastener the following year. This process required the operator to press a hole in the paper and then insert the fastener by hand. McGill went on to improve his device and demonstrate it at the International Exhibition in Philadelphia in 1876. Within one year, McGill patented a device capable of inserting and pressing a preformed fastener in one movement, but it still required the operator to load one staple at a time.

The name "stapler" can be found as early as 1888, but it wasn't until well into the 20th century that the term gained wide acceptance. The variety in names was due in part to the sheer diversity in materials and shapes used to bind papers together beyond the

now-standard staple. This included staples cast from spools of wire or strips of flat metal, along with straight pins and bent pieces of wire. In 1909, a device was patented by the Clipless Paper Fastener Company that joined documents by punching a hole and burr straight through the papers. The variety of shapes, calibers, and materials of staples contributed to the transformation and standardization of the stapler during the 1930s and 1940s.

By and large, each type of stapler offered on the market used a variety of staple unique to that particular model, a situation that proved inconvenient from the perspective of office supply as well as product marketing. An office that had difficulty in obtaining particular staples or desired to upgrade devices would have to take into consideration the accessibility of particular calibers of staple; meanwhile, a company that could offer a staple interchangeable with other models could gain a competitive edge. The answer to this problem was developed in part with the first "magazine" stapler patented as early as 1878. By the late 1920s, a magazine of over 100 glued, attached staples could be easily inserted into a stapler. The introduction of standard calibers of staples in 1940 made the convenient and rapid-fire magazine stapler the dominant fastener in American offices.

Traditional needle and thread or adhesives, along with the new generation of staplers, still presented the problem of documents being damaged should the owner decide to separate them at a later date. This need was rectified by the invention of the modern paper clip by William D. Middlebrook of Waterbury, Connecticut, who was master mechanic for over 30

years at the Oakville Pin Company. While in this capacity, he patented a paper clip along with a machine to create it in 1899.

The “classic” paper clip or “letter clip” is a bent metal wire that fastens papers by exerting pressure rather than perforating a hole, and it can easily be removed without damaging the paper and stored without becoming tangled with other clips. George McGill, already recognized for his work in developing the fastening staple and other office equipment, also patented a paper clip in 1903. Cushman and Denison, a manufacturer of metal products operating in New York City, obtained manufacturing rights from Middlebrook and marketed the paper clip under the name “GEM.” A number of clips of different shapes were marketed in Great Britain and Europe under the “gem” name, which had some influence in office supply circles in the United States. Paper clips are sometimes referred to as “gem clips” based on this nomenclature.

Another version of the paper clip popular in American offices was the “gothic” variety patented in 1934 and sometimes referred to as the “perfected gem paper clip.” Its pointed sides resemble the buttresses of a cathedral or the arches of a gothic window in comparison with the rounded, “Romanesque” edges of the classic paper clip. Despite the variety of patents granted for different shapes and materials, paper clips by 1940 remained similar in design to those introduced at the turn of the century.

Edwin Moore founded the Moore Push-Pin Company in 1904 in Germantown, Pennsylvania, just outside of Philadelphia. Moore invented the pushpin in 1900, and his company continues to develop office equipment that he originally developed, including picture hangers and map pins. Thumbtacks are typically referred to as “drawing pins” when used to attach work to drawing boards in drafting. During the 1920s, the concept of the mechanical stapler and the pushpin were combined with the Pinzit machine, which inserted a straight pin through paper by means of a special push device.

The development of adhesive tape for office environments began with the innovation of masking tape by Richard Drew for the 3M Corporation (the Minnesota Mining and Manufacturing Company) in 1925 in St. Paul, Minnesota. Masking tape was

invented for the painting needs of the automotive industry, where an even and clean-peeling adhesive was essential for painting and trimming parts of cars. The principle of a clean adhesive on a convenient roll was a significant development and gained in popularity. Clear, cellophane tape was also originally intended for industrial purposes; in this case, the need to waterproof parts to be used in train cars. Drew experimented with rolls of cellophane originally intended as a material for packaging his masking tape. By 1930, the first rolls of cellophane tape were marketed under the trademark “Scotch Tape,” which has entered into common American English as a colloquialism for any brand of cellophane tape. At the time of the product’s creation, “scotch” was a slang word for “cheap” or “stingy,” alluding to an incident during the product testing of masking tape where Drew was asked by testers to add more adhesive to his tape.

Mechanical calculators or adding machines have a long history as a favored pursuit of philosophers and inventors for centuries. It was not until the middle of the 19th century that a durable, mass-produced mechanical calculator entered the market. French entrepreneur and inventor Charles Xavier Thomas de Colmar created the “Arithmometer” in 1851. Contained within a wooden box, an Arithmometer could directly add or subtract numbers and perform long division and multiplication by means of a series of adjustable levers.

Improvement in interface, particular the addition of numbered buttons, marked the transition to “modern” mechanical calculators. Dorr Felt, an industrialist and inventor based in Chicago, Illinois, invented the first key-driven mechanical calculator in 1886 and named it the “Comptometer.” As opposed to the arithmometer, which required the operator to turn additional levers to complete a function, the Comptometer automatically calculated after one pressed the numbered keys. It possessed a keyboard of eight columns with nine keys each, which further allowed the operator to enter all the digits of a large number simultaneously. The device could add and subtract directly, but it required a series of additions and subtractions to multiply or divide. This ease of use allowed the Comptometer to maintain a level of prominence in the office

even after the innovation of electric calculators in the middle of the 20th century.

Felt brought his invention to the Chicago businessman Robert Tarrant, and together they founded the Felt & Tarrant Manufacturing Company and mass-produced the Comptometer in its varying stages of evolution. The company marketed the Comptometer until its merger with Victor Adding Machine Company in 1961, a point that marked a slow evolution of the calculator industry to electronic models. A Comptometer was roughly the size of a shoebox and made of polished metal, with rows of buttons on the top along with a number display and a small lever to the side that cleared the results when pulled. The introduction of the clearing lever was advertised as “the machine gun of the office” in reference to the technological advances in rapid-fire weapons during the Great War. In the 1930s, a number of special electric-powered models were introduced, although they did not outsell the traditional mechanical Comptometers.

Machinist William S. Burroughs founded in 1886 what became the Burroughs Adding Machine Company to market his invention, a mechanical “calculating machine.” In 1892, he commenced distribution of a mechanical calculator capable of printing a paper copy of its tabulations. The Dalton Adding Machine was created in 1902 and was the first calculator to have only 10 numerical buttons. However, the Facit-T model created in 1932 was the first 10-key version to gain widespread sales and distribution. A longtime producer of calculators and typewriters for American offices, the Burroughs Company also marked an important transition point between mechanical calculators and the rise of modern mainframe computers.

Paper Bag

A version of the square- or flat-bottom paper bag in use today was invented in the 1800s by Margaret E. Knight (1838–1914). Knight rejected the notion that women ought to spend their lives in the home, instead devoting herself to developing inventions, an activity she had enjoyed for years. As a child, she worked in a textile factory, where she was fascinated with the mechanical looms and began devising methods for improving their safety. As a young adult, Knight took it upon herself to improve on the design of paper bags, which then lacked a square or “flat” bottom. Instead, early paper bags had “envelope bottoms” that could not be opened into a quadrangular shape and had to be held open while being filled. Knight successfully created and patented a machine for pressing square-bottom paper bags in 1871.

Today, square-bottom paper bags are widely used because they can stand up by themselves, allowing baggers to fill them quickly and efficiently.

Paper Clip

The paper clip, a piece of bent wire used to hold papers together, arose with the explosion of commercial paperwork that accompanied the Industrial Revolution.

Paper clips come in many shapes, but the most common is the oval-within-an-oval design first manufactured by the Gem company.

Before the paper clip, sheets of paper were attached together using a method similar to binding a book: a pair of small slits was cut through the pages so they could be tied together with string or ribbon. In 1835, straight pins made of steel wire became widely available and were sold by the pound as “bank pins.” Pinning documents was more efficient, and its smaller holes were less damaging. However, pinning had several disadvantages. In addition to pricking workers’ fingers, repeated unpinning and repinning damaged the document corners, creating a floppy “dog ear.” The steel pins rusted during periods of prolonged storage and stained documents. The paper clip evolved as a reusable method of holding papers together while it protected both the documents and users’ fingers.

Johan Vaaler (1866–1910), a Norwegian inventor and patent clerk, is frequently cited as the inventor of the paper clip. He designed a single-loop paper clip in 1899 and was granted a U.S. patent on June 4, 1901. The patent described a clip made of “a spring material, such as a piece of wire, that is bent to a rectangular, triangular, or otherwise shaped hoop, the end parts of which wire piece form members or tongues lying side by side in contrary directions.” In addition to fastening papers, Vaaler’s invention became a unifying symbol in Norway during World War II, when Norwegians wore paper clips on their lapels as a sign of unification.

However, Vaaler was not the first to file such a patent. The U.S. Patent Office had on file approximately 50 designs for metal paper fasteners. The first patent for a bent wire paper clip had been awarded to Samuel B. Fay in 1867. The document stated that the clip was meant to attach papers to delicate fabrics, but it could also be used to attach papers together. The Fay paperclip was a single, triangular loop of wire, with two ends protruding from the apex. The Fay design was first produced by D. S. Gorman of New York in 1896 and marketed as the “Clinch Clip.”

Vaaler’s single-loop, rectangular paper clip has been confused with the double-loop, oval Gem paper clip in use today. In the 1870s, the Gem Manufacturing Company, Ltd began producing a functional paper clip that had two full loops of wire, one inside the

other. The Gem model was never patented, but there is evidence that it was developed before Vaaler’s 1899 patent application. The Gem paper clip was advertised in 1894.

In 1899, William D. Middlebrook was awarded a patent for a machine for manufacturing the Gem paperclip, and in 1904, Cushman and Denison registered a trademark for “Gem Paper Clips.” The announcement claimed that the Gem clips had been in use since March 1, 1892.

It is unknown who invented the Gem paper clip, but it remains the most popular paper fastener today. The original design met many of the criteria sought by office personnel: the double loops slid easily onto documents without mutilating the pages and prevented the clips from becoming tangled together in the box. The flat, thin wire wires made them inexpensive to purchase, took up less space in files, and required less postage to mail. Subsequent patents sought to improve upon the Gem by adding serrations to hold papers more securely, but the general design remains in use today.

Phonograph

In 1877, Thomas Alva Edison (1847–1931) invented the phonograph, which was a way of recording and playing back sound for the first time. Phonograph technology had many practical uses. However, its entertainment value soon took center stage. In this regard, Edison, his team of assistants, and his competitors laid the foundation of the music-recording industry.

Thomas Edison, pictured here in 1878, invented the phonograph, or gramophone, in 1877. While other similar devices could record sound, Edison's was the first to reproduce sound. (Library of Congress)

Edison was not the first person to invent a machine for recording sound. In 1857, a Frenchman named Édouard-Léon Scott de Martinville invented a device that could record sounds by making visual images of sound waves. However, de Martinville's phonautograph (as he called it) could not play back the audio it captured. Other inventors had also created a method of representing sounds on punch cards that were used to program organs and for various other musical instructions.

Edison's work with sound began in the 1870s with his interest in recording telegraph signals. He devised a machine with a turning cylinder covered in wax and a needle that would vibrate and create impressions on the wax in response to telegraph signals. His experiment failed, because the machine was incapable of accurately discerning between the dots and the dashes. However, Edison noticed that the wax impressions generated an audible hum when he reversed the

procedure. He immediately realized that he had made an accidental breakthrough in sound playback.

In 1877, he and his lab assistants at Menlo Park, New Jersey, designed the prototype of what he called the phonograph (or sound recorder). The design of his new machine was almost identical to that of his previous one except that he replaced the wax paper with tinfoil, and he added a microphone. The sound quality was poor, but it successfully played back the first audible human voice: Edison's recitation of a nursery rhyme ("Mary Had a Little Lamb"). Edison, a veteran inventor, was amazed when he heard the recording of his voice for the first time. He filed for a patent for the phonograph in December 1877, and he received it two months later. With patent in hand, he established the Edison Speaking Phonograph Company (ESPC) as a way to profit from the new device.

Edison suggested several uses for his new invention. Among them were dictation, to save time in office work; audiobooks for the blind; elocution, a way to learn how to pronounce and articulate clearly; music recording, a way of listening to past performances; family record, a way to record sayings or reminiscences of family members in their own voices, including the last words of dying family members; as a music box or musical toy, as clocks that announced the time, such as when to go home or to go to lunch, in articulated speech; preservation of languages by recording them with exact pronunciation; educational purposes or recording a teacher's explanation of a certain subject so that a pupil could refer to the recording when and as many times as needed; for recording a teacher's correct spelling of words so that students could listen to it as many times as necessary and commit the correct spelling to memory; and connection to the telephone as a way of recording communications.

The immediate public reaction to Edison's device was overwhelming. Many amazed reporters descended on his lab for demonstrations. Many people who witnessed the invention and others who read about it compared it to magic. In fact, the popular press nicknamed him the "Wizard of Menlo Park." He was invited to Washington, D.C., to demonstrate the phonograph to the astounded President Rutherford B. Hayes and the U.S. Congress. As a way of creating a permanent

audiohistorical record, Edison asked famous people from his time to record messages on his phonograph. One of the participants was England's Queen Victoria. However, the novelty of Edison's phonograph prototype wore off quickly with the public.

By the 1880s, Edison paused his work with the phonograph to concentrate on designing and building power stations in New York to provide residents with electricity to power lightbulbs (the invention for which he is most remembered). Alexander Graham Bell (1847–1922), the inventor and patent holder of the telephone, decided to perfect Edison's phonograph technology. Edison's tinfoil phonograph design produced poor-quality audio. The cylinder could only record for about two minutes, and it deteriorated after two or three uses.

Bell set up a lab with assistants in Washington, D.C. He replaced Edison's hand crank system with a foot lever (or treadle) that imparted motion to the machine, and he replaced the tinfoil with a much more durable, wax-covered cardboard. Bell's changes and improvements in sound quality and durability garnered him a patent for his graphophone. However, Bell was still not satisfied with his progress, and he invited Edison to cooperate with him to create a better machine. Edison, who believed that Bell had pirated his phonograph technology, refused the invitation. Instead, in 1888, Edison responded competitively by creating a phonograph with better sound quality and a lower price than the graphophone.

In spite of the many uses that Edison had proposed for his new invention, public demand for it mostly centered around its entertainment value. In large cities, people would put coins in music penny arcades or pay a nickel to gather in phonograph parlors to listen to music or vaudeville comedy monologues. By the turn of the century, the ESPC was competing with several other companies for a fortune in pennies and nickels. One of the ESPC's biggest competitors was the Victor Talking Machine Company (VTMC) established in 1901 by Emil Berliner (1851–1929), the inventor of the gramophone.

The ESPC's phonograph cylinder had one major drawback: it could not be mass-produced. This meant that individual cylinders had to be recorded one at a time, with musicians repeating their performance for

each cylinder recording. The disadvantage of time-consuming cylinder recording limited the size of the catalog of music that the ESPC could offer. It also resulted in different recorded versions of the same songs. Edison made the catalog selections based on his own taste in music. In contrast, instead of cylinders, the VTMC used recorded discs made from hardened rubber, which could be mass-produced. One tremendous advantage of the use of discs was that the VTMC's catalog of music offered a much wider variety of artists.

While Edison was focused on the use of the phonograph in public places (as well as the public arena for the motion picture industry, which he pioneered), the VTMC introduced the first home entertainment system—the Victrola, which played discs and projected sound with a horn-shaped speaker. The Victrola cabinet was equipped with a compartment where records could be stored, and it looked like a piece of living room furniture. An added feature was the ability to retract (or hide) the horn speaker.

Edison responded by placing a cylinder (that could be mass-produced and could play four minutes of music) in a home hand-cranked phonograph he called the Amberola. Edison remained convinced that the best way to gain a lead in the phonograph market was by creating a machine that could produce the best sound quality. In 1912, due to popular demand, the ESPC replaced the cylinders with discs. By 1915, the Amberola's fidelity was superior to all other home systems on the market. In advertisements, Edison boasted about the superiority of his discs by claiming that they could be played 1,000 times without wear. In spite of these improvements, the Victrola remained the more popular machine for several reasons.

Most important, the VTMC still offered a much larger record catalog. Also, most consumers found the Edison record cabinet less attractive than the Victrola's. In the past, Edison had been able to control his catalog sales by offering only cylinders while his major competitor sold discs. However, once Edison dispensed with the cylinders and adopted discs, he designed discs that would play only on Edison phonographs. Many consumers did not like the restriction. In the 1920s, static filled radio broadcasts, and home

radio sets became extremely popular. Edison believed it to be a passing fad. He was wrong. While the VTMC survived the radio craze, the ESPC did not: it went out of business in 1929.

Although Edison did not triumph in his phonograph competition, he was responsible for creating the primitive technology that greatly contributed to the birth of the music industry. In later years, various types of electronic phonographs were known generically as “record players” (or turntables). As early as the 1930s, exclusive record catalogs became obsolete when numerous record companies and record shops were established. More people than ever before were listening to music (and a greater variety of it).

After World War II (1939–1945), millions of American children (baby boomers) were born between 1946 and 1964. There were so many of them that people started calling them “teenagers.” Due to the affluence of the 1950s, many parents gave their children allowances—regularly supplied spending money. Teenagers, whose lives revolved around the music culture, viewed television programs, like *American Bandstand* (which featured teenagers showing off their latest dance steps), and then they rushed to their local shops to buy records with the latest songs that they then played and danced to at home. The demand for records led to many innovations in the booming record industry, including the creation of the long-playing (LP) record that included approximately 12 songs (6 on each side).

The demand also created an opportunity for new artists like the Hispanic Ritchie Valence; African Americans including Chuck Berry, Little Richard, and Ray Charles; and poor Southern whites, including Buddy Holly and Elvis Presley. The *Elvis’ Christmas Album* (1957) LP became the biggest seller of the 1950s, selling more than 7 million copies. The biggest-selling record of the 1960s was the double LP *The Beatles* (a.k.a. “The White Album”) (1968), selling more than 19 million copies. Record sales continued to rise in the 1970s and 1980s. Michael Jackson’s *Thriller* (1982) LP sold more than 30 million copies.

Although music remained a group experience with concerts and dances, home record players also made music a personal experience that one person could

enjoy alone. Unlike spontaneous live performances that often changed, records froze (or standardized) performances so that they could be heard exactly the same way each time the record was played. This allowed aspiring musicians or singers to play songs over and over until they learned them. This also changed many live performances, because audiences who were familiar with artists’ recorded work expected to hear the songs performed exactly the same way in a live setting.

Long after Edison’s death, all of the suggested uses that he proposed for his invention were realized: the use of recordings to facilitate office work, the creation of audiobooks, music boxes, musical toys, family diaries, talking clocks, educational recordings, answering machines, and music recording. Edison did not foresee that the entertainment value of the phonograph would be the greatest determinant in generating consumer interest. But, once he recognized this phenomenon, he attempted to capitalize on it. There were also some applications of his invention that he did not originally foresee. For example, by the late 1920s, motion pictures, which had been silent for years, benefited from the addition of recorded sound. Like Edison, others embraced the quest for a more perfect sound. These endeavors led to important developments, including stereo sound (distinct sounds directed through two or more speakers) in 1957 and digital music recorded on compact discs (CDs) in 1982.

Primary Document: Roll Call of Companies at the Phonograph Convention in Chicago (1890)

In 1890, the Phonograph Convention met in Chicago, Illinois, at the Auditorium Hotel. The following is a roll call of the companies represented at the convention. Note the diversity of geographic location, which suggests that the popularity of phonographs extended well beyond the large urban centers on the two coasts.

PHONOGRAPH CONVENTION. AUDITORIUM HOTEL, CHICAGO, ILL., May 28, 1890.

MORNING SESSION.

The chairman then appointed as committee on permanent organization, Messrs. Easton, Gottschalk and Stone. Motion for roll call was then unanimously adopted and the roll was thereupon called as follows:

The Alabama Phonograph Co., Anniston, Alabama; Mr. Chas. A. Cheever, President.

The Central Nebraska Phonograph Co., Kearney, Nebraska; E. A. Benson, Director.

Chicago Central Phonograph Co., 801 and 804 Home Insurance Building, Chicago, Ill.; Geo. B. Hoit, General Manager, E. A. Benson, Chas. Dickinson, Directors.

The Columbia Phonograph Co., 627 E Street, N. W., Washington, D. C.; E. D. Easton, President, R. F. Cromelin, Secretary, W. H. Smith, Treasurer.

The Colorado and Utah Phonograph Co., Denver, Colorado; S. W. Cantril, Manager, John Barber, Assistant Manager.

The Eastern Pennsylvania Phonograph Co., 130 South Fourth St., Philadelphia, Pa.; Jas. O. Clephane, Secretary.

The Florida Phonograph Co., Jacksonville, Fla.; J. C. Clarkson, Superintendent.

The Georgia Phonograph Co., 43 Walton St., Atlanta, Ga.; J. C. Clarkson, Superintendent.

The Iowa Phonograph Co., Sioux City, Iowa; Whitfield Stinson, Secretary.

The Kansas Phonograph Co., Topeka, Kan.; Geo. E. Tewkesbury, President. The Kentucky Phonograph Co., Louisville, Ky.

The Metropolitan Phonograph Co., 257 Fifth Avenue, New York City, N. Y.; Chas. A. Cheever, President, Felix Gottschalk, Secretary.

The Michigan Phonograph Co., 15 & 17 Detroit Opera House, Detroit, Michigan; W. H. Freeman, Manager, C. W. Swift, Secretary.

The Minnesota Phonograph Co., 108 Rochester Block, Minneapolis, Minn.; C. H. Chadbourne, General Manager. A5 Missouri Phonograph Co., 416 3rd Avenue, South, Minneapolis, Minn.; J. C. Wood, W. J. Wood, Geo. L. Wood, A. W. Clancy, Vice-President, J. C. Elliot, General Manager. The Montana Phonograph Co., Helena, Montana; E. A. Benson, Director. The Nebraska Phonograph Co., Omaha, Nebraska; E. A. Benson, President. The New England Phonograph Co., Boylston Building, Boston, Mass.; A. N. Sampson, Manager. The New Jersey Phonograph Co., 758 Broad Street, Newark, N. J.; W. L. Smith, General Manager. The New York Phonograph Co., 257 Fifth Avenue, New York City, N. Y.; John P. Haines, President.

The Ohio Phonograph Co., 220 Walnut Street, Cincinnati, Ohio; Jas. L. Andem, President.

The Old Dominion Phonograph Co., Masonic Temple, Rooms 8 and 9, Roanoke, Va.; J. H. McGilvra, President. The Pacific Phonograph Co., 323 Pine Street, San Francisco, Cal.; Louis Glass, General Manager.

The South Dakota Phonograph Co., Sioux Falls, Dakota; Henry Lacey, General Manager.

The Spokane Phonograph Co., Spokane Falls, Washington; Louis Glass, Director. State Phonograph Company of Illinois, 804 Home Insurance Building, Chicago, Ill.; G. Farwell, W. H. Hubbard and Ed. Lobdell, Directors.

The Texas Phonograph Co., Galveston, Texas; H. L. Sellers, President, Thos. Conyngton, General Manager.

The West Coast Phonograph Co., Portland, Oregon; Louis Glass, Director.

The Western Pa. Phonograph Co., 146 Fifth Avenue, Pittsburgh, Pa.; J. H. Friend, Secretary.

The Wisconsin Phonograph Co., 414 Broadway, Milwaukee, Wis.; Henry D. Goodwin, Secretary; W. S. Burnett, Superintendent.

The Wyoming Phonograph Co., Cheyenne, Wyoming; E. L. Lindsay, Manager

Photographic Film

Photography began with the usage of heavy, wet plates that captured images of subjects and that required processing to fully develop the images. These wet plates paved the way for the creation of photographic film through experiments with chemicals that later helped refine the images' resolution. Photographic film is a plastic strip coated with gelatin emulsion, a chemical creation invented by Richard Leach Maddox. The gelatin emulsion determines the sensitivity, contrast, and resolution of the film depending on the size and characteristics of the light-sensitive halide crystals embedded in it. Louis Daguerre, a French painter and inventor, created the earliest photographic process, and it influenced the American photography industry.

In 1939, Daguerre introduced his photography technique, which became known as "daguerreotype." It did not use film but used liquid iodine as the light-chemical reactive and copper plate as the base for photographs. The daguerreotype was cumbersome to use due to the heavy plates and the box-type camera, but the invention was revolutionary and was adopted worldwide. Mathew Brady, an American photographer, recognized as the "father of journalism," learned the daguerreotype process from Samuel F. B. Morse, an American inventor famous for his work on the telegraph.

Brady photographed historical figures such as Abraham Lincoln and Robert E. Lee, but most important, he captured real-life moments on the battlefields of the Civil War (1861–1865). His process consisted of planting the camera, focusing the lens, coating the plate, and developing the image while it was still wet. Although it was an arduous process, his images have great historical value; they exposed the never-before-seen truths of this gruesome war. The thin glass plates were coated with photographic emulsion; this provided better optical quality but did not solve the problem of carrying bulky plates. It was not until 1885 that the United States was introduced to the first flexible photographic roll film.

Born on July 12, 1854, American entrepreneur George Eastman founded the Kodak Company, which introduced the new innovation of roll film in May 1885.

Eastman's first film was composed of an image-bearing layer attached to a sheet of hardened, clear gelatin. Four years later, Eastman improved the photographic roll film by utilizing nitrocellulose ("celluloid"), a flammable compound now termed "nitrate film," to introduce his newly refined transparent plastic roll film. Although the nitrate film was hazardous, it had the advantages of being durable, slightly more transparent, and cheap. This was a huge development that encouraged many to explore photography.

Eastman utilized an early photographic process called "calotype," invented by Henry Talbot, and gelatinous silver nitrate plates, invented by Richard Maddox. He provided consumers with a simple box camera and a 100-exposure roll of film. Once all the exposures on the film were completed, the consumer would send the entire camera to the factory in Rochester, New York, and wait until the camera was sent back with a reload of film. Meanwhile, the first film was at the factory to be developed. The greatest advantage of this camera was its simplicity. Kodak's advertising slogan was "You press the button, we do the rest." Although the camera was introduced at a high price of \$25, it mainly attracted amateurs who were excited to capture spontaneous moments with a series of pictures. In 1900, the Brownie camera was introduced, this time at the low price of \$1. Eight years later, Kodak introduced cellulose acetate, also known as safety film, for usage in 16-mm and 8-mm home movies as well as for x-ray film.

As photographic film improved, instant photography gained popularity. The camera and film no longer required additional chemicals or equipment. Instant film was introduced by Polaroid. Film maintained its popularity until the 21st century, when digital cameras became accessible to consumers. The first digital camera was released in 1989 as the Fuji DS-X. This innovation also promoted the development of photography software and color printers. Film has not been completely abolished; it continues to be used by photography enthusiasts who prefer the unique look that a film photograph has.

Pipe Wrench

A pipe wrench is a tool with an adjustable jaw that allows it to lock onto the pipe being repaired; any forward pressure on the handle pulls the jaws together. Solymon Merrick, an American entrepreneur, patented the first wrench, originally called the "spanner," in 1835. As the wrench continued to progress through small innovative ideas, Daniel C. Stillson, a steamboat engineer and American inventor, patented the pipe wrench in September 1870. Stillson reached out to Walworth Company to put it into production, but he had to design a working prototype first. The pipe wrench user aims to maintain a firm grasp on the pipe without jerking the wrench, as the handle can either tighten or loosen it. Stillson's tests of the wrench proved to be successful, and the production of the pipe wrench commenced.

Stillson worked as a cotton picker in New Hampshire before the Civil War. During the war, he was offered a position as an acting third assistant engineer for the navy. He worked his way up to acting first assistant engineer. After leaving the navy, Stillson moved to Mississippi to live with his family and worked for the Walworth Company. Around this time, he and his cousin applied for U.S. patent number 50,748 for the pipe wrench. After some improvements, they received U.S. patent number 95,744. Initially, the cousins were going to sell their invention for only \$2,500, but their employer advised them not to. At the time, Stillson believed that \$2,500 up front was a better deal than royalties, but over his lifetime, he received about \$80,000.

The wrench had one swivel jaw to prevent it from loosening as its handle was turned. It also included a screw knob, used as a security measure to maintain a lock on the bolt or pipe. It could adjust to any size of bolt. With enough pressure and torque, the wrench was capable of a full 360-degree rotation. During production, the Walworth Company credited Stillson by engraving his name on the wrench. The Stillson pipe wrench became a fast-selling commodity, and in 1905, other companies made "Stillson" and "Stillson pattern" wrenches shortly after his patent expired. These wrenches usually included minor changes to their material, size, and handle design.

Daniel Stillson revolutionized the way people work in factories, since the pipe wrench made it easier for laborers to loosen and tighten bolts.

Player Piano

The player piano is a self-playing piano. It was popular during the late 19th and early 20th centuries. It peaked in popularity 1924 and then went into a sharp decline due to improvements in phonograph recording.

Henri Fourneaux invented what he called a "Pianista" in 1863. Fourneaux's piano was the first with a pneumatic mechanism and it was introduced at the Philadelphia Centennial Exhibition in 1876. Several American inventors contributed to the player piano's evolution, including John McTammany, Frank Van Dusen, and Henry and William Schmoele.

In 1910, the player piano was advertised in a highly profitable campaign that used a full-page color advertisement that cost \$250, which in 2016 is equivalent to \$7,200. By the 1920s, the piano player had reached its peak. In the United States, perhaps more than half of all pianos made were player pianos.

Player pianos come in several types. Most are “split stack control” instruments, meaning that operating mechanisms can be found both above and below the keyboard. Many split stacks allow operators to change volume on all or part of the keyboard. “Theme control” instruments have pneumatic systems that allow part of the score on a roll to be emphasized over other parts. “Isolated theme” pianos pick out particular melody notes, while “reproducing” player pianos are fully automated. These last are the type most often thought of as player pianos. Fully automated, or reproducing, pianos require no human interaction. Instead, a roll is inserted into the instrument, and an operator turns it on, allowing the piano to play a piece of music independently of human hands.

Related to the player piano is the orchestrion, which combines piano, organ, percussion, and other instruments. Orchestrions were generally used in commercial settings such as fairs, circuses, and music halls. They were replaced by the more versatile, smaller, and more affordable jukebox by the mid-20th century.

Musical rolls for player pianos include the hand-played roll and the word roll. The hand-played roll added musical phrasing to the musical roll so that pianists had some help with tempo. Word rolls included the words to songs, usually printed in the margins of the roll.

It was not until October 1929 and the Wall Street crash that the piano player started its sharp decline. Between the 1930s and 1950s, many player piano companies closed their doors and their factories. Some of the final rolls for player pianos were issued in the late 1930s. By 1940, many factories had stopped making new classical rolls. In the 1950s, many collectors started to rescue player pianos, and in the late 20th and early 21st century, there was a small revival in them, particularly in their reconstruction and reproduction.

Portland Cement Mortar

Portland cement mortar, an adhesive that adheres bricks together to create structures, was created and patented on October 21, 1824 by Joseph Aspdin, a British cement manufacturer from Leeds. It is called Portland cement because of its similar appearance to a limestone quarried on the Isle of Portland in England. The cement revolutionized engineering and architecture around the world. Although the product originated in England, the rest of the world mimicked and improved on Aspdin’s invention in the century after its creation.

Aspdin experimented with different substances and mixtures to produce a cement that would outperform other cement-like products in every critical category. Portland cement is created with crushed limestone put into one entry of a kiln while coal dust is added through another entry. High temperatures help infuse the coal dust into the ground limestone to create lumps that are put into containers and immediately exposed to steam. The lumps go through a grinder a second time to further pulverize them and create the distinctive, gray powdered cement we see today.

The United States was falling behind in the cement-manufacturing business, manufacturing “natural” cement. Portland cement took over the market, and it was adopted in the United States. Experiments done in the United States to improve on the product eventually put American cement at the top of the

international cement market. The Portland Cement Association was created to research and continue experimentation.

With the growing improvements in and understanding of cement, as U.S. industry expanded, the perfect moment for Portland cement was its use in creating new U.S. infrastructure. Prior to the 1920s, roads and pavements were made up of less than 1.5 percent cement, but the amount grew to 20 percent, and the new cement was used frequently in the construction of other institutions such as schools and hospitals.

Portland cement turned out to be cost-efficient while maintaining its strength and versatility. Without Portland cement, our highways, roads, and sidewalks would all be less stable. Portland cement was a great factor in the growth of U.S. industry as cities expanded around highways and roads, and it allowed the entire country to become connected.

Punch Card Tabulator

Prior to the creation of the punch card tabulator, the United States had the tedious task of handwriting the U.S. census. During the 1880 U.S. census, clerks

Herman Hollerith built the first punch card tabulating machine in the late 1880s. The 1890 census took only one year to tabulate using this machine, compared to the eight years it took to count the 1880 census. (Library of Congress)

employed by the Census Bureau took years to compile and record all the census information. This was one result of an influx of immigration along with a population boom. Realizing that this method was inefficient and costly, some within the bureau proposed an invention that could record the information efficiently. Herman Hollerith, a clerk working in the bureau, was the eventual inventor of the punch card tabulator, patenting it under the title "Art of Compiling Statistics" on January 8, 1889.

Although punch cards were already in use by train clerks, Hollerith wanted to create a machine that could both assemble and store data. His machine had three different sections. The first section, the "press," read the data from the cards. The second was "the counter," and last was the "sorting box."

To organize the information the machine gathered, Hollerith began with a "templet," or pattern, that listed

the name or characteristic of an individual in a certain order. The templet contained several categories of individual characteristics, such as a person's age, country of origin, gender, etc. The templet had 288 holes available to be punched. The second step was to collect and compile all the characteristics of an individual on a strip of paper. The person would place this strip, or "tablet," into the machine. The data recorded on the strip would then be transferred onto the punch card tabulator. As the paper ran through the machine, the data was recorded based on the holes punched. This is done by having "circuit-controlling index-points" in "a fixed relation to each other." To put it simply, the paper or templet acted as a barrier between the index points. When the paper passed through the machine, wherever there was a hole punched in the paper, an electrical circuit registered as a result of an "opening" in the barrier, which caused the index points to close the circuit.

The third and final step was to transfer the stored information transferred onto a new templet. Based on corresponding numbers from the initial recording, the machine registered the characteristics of the individual. The system could store population information for the U.S. Census as well as registrations of any kind, such as births, deaths, and marriages. This Hollerith's "counting-machine" was built of a metallic drum with pointers or pins that were insulated and required electricity to function.

Once the punch card tabulator was approved by the patent office, however, the Census Bureau became a bit hesitant to use it for the 1880 census, as it believed that the machine would interfere with all the work they had already completed. In the end, it decided to take the risk and test the tabulator. Hollerith's invention helped the Census Bureau to improve its operations by saving time and money while improving statistics keeping. Hollerith was rewarded for his amazing invention: the Franklin Institute of Philadelphia awarded him the Elliot Cresson Medal for his success. The punch card tabulator is considered one of the first "modern" computing systems.

Quadruplex Telegraph

In 1874, Thomas Edison created one of his most important telegraph inventions ever, the quadruplex telegraph—which could send four telegraph signals at the same time. This was much more efficient than its predecessors, the duplex and diplex, which were only capable of sending two signals at a time. Edison was actually instructed by Western Union to invent a more efficient telegraphic machine to save the company money in the future.

Edison had made enough of a name for himself that Western Union desired his skills in telegraphy. Western Union invested in buying out as many telegraph patents as possible to have advantage over its competition. It made sense for both sides to work with each other, as Edison had for years worked on solving the puzzle of sending two messages over one wire at the same time. Edison was given resources from Western Union to experiment on the issue while the company reaped the benefits by owning the rights to the quadruplex telegraph.

As Edison began work on an efficient telegraphic machine, he experimented with previous telegraphs such as the duplex and diplex. He soon discovered that incorporating the duplex and diplex with each other, he could send four messages concurrently on one wire. To do this, Edison employed an ingenious method that he had used in prior telegraphic projects. He created a polarized relay to react to any shifts in polarity from a current while the other "normal" relay reacted to the

strength of the current. This allowed for the relays not to overload or be placed in a difficult situation to react to either the strength of a current or its polarity. Once Edison solved this problem, he introduced the invention to Western Union, which paid him \$10,000 for it. The quadruplex telegraph had become his most lucrative invention.

Edison's invention allowed telegraph companies like Western Union a wide range of opportunities. Many messages sent over a single line lowered the time in which messages were received or sent and meant less traffic on the wires. Messages with different topics could even be sent simultaneously to a recipient, who no longer had to wait to receive the next message. The quadruplex telegraph benefited everyone by making communication simpler. Important or urgent messages could be sent faster and to more people. Telegraph companies had more lines available for other uses, so they began renting or leasing their lines to interested customers.

Even though he had signed a contract, Edison sold his patent rights to a Jay Gould prior to the offer given by Western Union. This led to a court battle between Gould and Western Union over the rights. Both sides knew how important the quadruplex telegraph would be. The courts ruled in favor of Western Union, as it had a signed contract. The invention saved Western Union tremendous amounts of money and allowed it to keep up with the growing popularity of sending messages.

Railroad Refrigerator Car

The first U.S. patent for a refrigerated railcar was granted to John Buie Sutherland (1825–1895) of Detroit, Michigan, on November 26, 1867. Gustavus Swift (1839–1903) improved on Sutherland's design, and the Swift-Chase refrigerated car became the industry standard for decades. Mechanically cooled cars, as opposed to ice-cooled cars, were developed in the 1950s.

As demand for beef rose among consumers in the major urban markets of the United States, meatpackers sought ways to centralize and economize meat processing. Railroad cars had long been used for shipping live cattle, but there were many inefficiencies involved in this practice—the cattle lost weight during long trips and had to be watered and fed at stops along the way. Also, 60 percent of the weight of a live animal represented waste or inedible by-products.

John Sutherland, an immigrant from Scotland, was a master car builder for the Michigan Central Railroad. He knew that ice had been used to cool shipments of milk, butter, poultry, and seafood since the 1840s. On that principle, Sutherland developed a car with ice bunkers at each end and vents in the floor that helped the air to circulate. A significant limitation of his design, however, was the fact that the car could only be reiced when empty. Sutherland could not find investors willing to back his plans to build the cars, so little came of his patented design.

Another Detroit resident, William Davis, built a car with some improvements on Sutherland's design in 1868, and meatpacker George H. Hammond used it. Hammond built a major meatpacking plant in northern Indiana and founded the city of Hammond in the process. In the early 1880s, Hammond had 800 refrigerated cars in service and was processing 100,000 head of cattle per year.

Gustavus Swift was in the meat business in New England and sought more efficient ways to transport

meat from the vast stockyards of Chicago to Boston and other Eastern cities. In 1878, he hired a Boston engineer named Andrew Chase to design a refrigerated car. Chase's car was a considerable improvement over previous designs. It was well insulated, had ice bunkers near the roof of the car that could be replenished from the outside while the car was loaded, and had a forced-air ventilation system to keep the cold air circulating around the meat.

Nonetheless, most railroads, which had already made huge investments in stock cars for shipping live cattle, showed little interest in the refrigerator car. Swift mortgaged most of his own property to get the first of his cars built by the Michigan Car Company in 1879. This design, known as the Swift-Chase car, became the standard refrigerated rail car in the United States until well into the 20th century. Because railroads in the eastern part of the country were reluctant to haul his cars, Swift made a deal with a Canadian railroad, the Grand Trunk Line, to move his cars through Canada to the eastern U.S. markets. By 1880, Swift had more than 200 cars in service and was shipping 3,000 beef carcasses from Chicago to the East Coast weekly. Because the ice in the cars had to be replenished along the way, facilities had to be built for making ice and for packing the ice into the cars. Swift estimated that an equal amount of ice was needed for the weight of the beef being shipped. Even with this expense, however, he could ship three dressed beef carcasses for the cost of shipping one live animal.

As the railroads eventually embraced the new technology, many other meatpacking companies built their own fleets of "reefer" cars, and refrigerated cars were also used in shipping fresh vegetables and fruits. Many railroads created subsidiary companies to operate their own fleets of refrigerated cars. In the 1950s, cars equipped with mechanical refrigeration units began to replace the ice-cooled cars, but about the same time, similar technology was invented for trucks, and the trucking industry began to capture most of the movement of refrigerated cargoes.

Railroad Sleeping Car and Pullman Car

Though popularized by George M. Pullman (1831–1897), the railroad sleeping car predates Pullman's cars by 20 years. Pullman designed the most widely used cars and created the system of contracting with the major American railroads to operate his sleeping cars and dining cars on their lines. By the early 20th century, he had a virtual monopoly on the sleeping car business in the United States, and the name "Pullman" had become synonymous with quality sleeping car service.

Several eastern railroads were offering sleeping car service in crudely designed cars by the 1830s and 1840s. Generally, customers found these cars cramped, dirty, and poorly ventilated. Most simply had bunks built along their sides, which were useful only for sleeping, and the passengers would ride in other seats during the daytime. A key element in the design of Pullman's cars was convertibility—the cars could be used as chair cars in the daytime, and the same seats were converted into sleeping berths for nighttime travel, with an additional overhead berth. Over time, the Pullman firm designed many different styles of sleeping cars with different levels of comfort and privacy that could be offered to the traveling public at various fares—but the backbone of the Pullman fleet was the open-section sleeper, a car with 12 sections with an upper and lower berth in each section. Pullman staffed these cars with porters who were hired from among freed African American slaves; he believed that former slaves who had been house servants would know how to give professional service to passengers.

Pullman was born in Albion, New York, in 1831. He worked with his father as a carpenter and in moving houses. In 1855, he moved to Chicago and gained a reputation as an expert in raising buildings to meet new street levels. In 1858, he contracted with the Chicago and Alton Railroad to convert three day coaches into

sleeping cars. Although these cars were well received by customers, the railroad did not order any more conversions. After spending some time in Colorado during a mining rush there, Pullman returned to Chicago and convinced the Chicago and Alton Railroad to allow him to build a completely new sleeping car rather than making conversions as he had previously.

In 1865, he built the Pioneer—a large, elegant car to provide comfortable sleeping arrangements for travelers. The car was wider and taller than normal railroad equipment and might never have been adopted as a standard were it not for the favorable publicity Pullman received when the car was used in President Abraham Lincoln’s funeral train. The Lincoln family rode in the car during the trip from Washington, D.C., to Springfield, Illinois, in 1865.

Pullman raised \$1 million in capital by selling by selling stock to railroad executives and industrialists. The Pullman Palace Car Company was incorporated in Illinois in 1867. Pullman patented some of his designs for sleeping and dining cars in 1869, and he bought the Detroit Car and Manufacturing Company to use as a plant for building his cars. In 1880, Pullman built a new factory and the town of Pullman on a 4,000-acre site south of Chicago.

Over time, Pullman bought many competing companies, and in 1889, his purchase of the Wagner Palace Car Company, which had been building sleeping cars for the New York Central Railroad and other eastern lines controlled by the Vanderbilt family, was a major step toward control of virtually all the sleeping and dining car business on American railroads. By 1910, all of Pullman’s competitors had either been merged into his company or gone out of business. Besides sleeping and dining cars, the Pullman Company also built mail cars, refrigerated cars, streetcars, and a variety of freight cars.

The key to Pullman’s success was providing high-quality service, plus the fact that he operated the sleeping and dining cars for the railroads rather than simply building and selling the cars. He called this means of doing business the “Pullman system.”

Railroad Switch Systems

A railroad switch, also called a signal switch, is a mechanical system that allows trains to change tracks. Charles Fox patented the first such switch in 1832.

Fox used a system of rods and levers for a signal box that would direct the movement of the trains by use of sliding rails. Fox used a stub switch, or the blunt ends of railroad tracks (track ends lacking the now-common tapered ends found at switching conjunctions). This switch system was not suitable for high speeds, so trains had to slow down to switch tracks. Stub switches are also monodirectional: trains can go only one way on the switch, and a reversal of direction would cause a derailment.

After the Civil War, George Westinghouse recognized the need for better signaling devices once the development of rail yards increased, and that is when he developed the interlocking switches. The very first searchlight signal was created in 1869 by Thomas Hall and produced by the Hall Signal Company. By acquiring this company, Union Switch and Signal was able to produce its own searchlight models based on Thomas Halls’ invention.

In 1881, George Westinghouse combined the Union Electric Signal Company and the Interlocking Switch and Signal Company to make Union Switch and Signal (US&S). This allowed Westinghouse to take advantage of track circuits and interlocking. Interlocking uses a number of signals to prevent dangerous and conflicting movements on the tracks and is designed so that the display of a signal is impossible unless a certain route is proven clear and safe. Eventually, US&S was able to procure the Hall Signal Company that allowed them to own the patents for searchlight signals.

In 1882, the very first power interlocking system was created in the United States by US&S, and 30

years later, it developed an electropneumatic system that used electricity, pneumatic pressure, and hydraulic pressure. The pneumatic pressure set the safety signals and threw switches; electricity ran the valves that regulated the signals, and hydraulic pressure activated the valves that regulated the switches. Failures could occur within this system, though, and they were only noticeable when there was an attempt to change a control element's setting.

Today's railroad switch systems are powered by electricity and are managed by electronics. Turnout speeds, the speed at which a train might take a track switch, have increased dramatically, with some modern switching systems able to allow speeds up to 80 miles per hour.

Richards, Ellen Swallow (1842–1911)

The “First Lady of American Science,” Ellen Swallow Richards, founded the science of ecology as well as the study of home economics. The first woman to graduate from the Massachusetts Institute of Technology (MIT) in chemistry, Richards was concerned with the growing pollution associated with the industrial age in America. Her work set standards for clean air, pure water, and an uncontaminated food supply. Modern public health experts credit her improvement of sanitation as a key factor in the increased life expectancy of Americans from 47 years in 1900 to 75 years in the mid-1990s.

Richards was born in 1842 to Peter Swallow and Annie Taylor, who had a small farm in Massachusetts. The Swallows, as former teachers, were dissatisfied with the education available to girls and taught their

daughter at home. Richards's formal schooling began when her father located a high school, Westford Academy, that accepted female students. The family moved to Westford, Massachusetts, and purchased a small grocery store. At school, Richards excelled in mathematics and German. At home, she nursed her mother and learned how to run a business by doing the accounting and inventory for the store.

Richards spent two and a half years working as a nurse, tutor, cook, and housekeeper to earn the \$300 needed to attend Vassar College, which she entered at the age of 26 as a third-year student. She excelled at astronomy, studying with Professor Maria Mitchell, who was also a pioneer in American science and a role model for young women who wanted to pursue careers in science. Ultimately Richards decided that chemistry, with its practical applications for improving the environment and human quality of life, would be her life's work.

In 1870, laboratory positions were not open to female chemists. Richards unsuccessfully applied to firms in Boston, Philadelphia, and Dayton. One firm suggested that she apply at the Massachusetts Institute of Technology. Richards's references from Vassar convinced the admissions committee to grant her entrance to MIT as a “special” student. Richards was not charged tuition, and she later learned that she was not included on her class rosters either. The admissions committee had created the “special” status to protect MIT from protests against opening its doors to women.

As an undergraduate student, Richards was in charge of a water sewage study commissioned by the Massachusetts Board of Health. Her results became the standard for Massachusetts's water purity and established Richards as an international expert in water quality analysis. When Richards graduated in 1873, she was not only MIT's first female graduate but also the first woman in the United States to graduate with a degree in chemistry.

Richards met her husband, mineralogist Robert H. Richards, when he asked her to translate an important German mineralogy text. Robert proposed marriage while they were working together in his laboratory. She accepted two years later, once he convinced her that he would not interfere with her scientific career. Married in 1875, they had no children and devoted themselves

to supporting each other's research. While Richards did not have access to graduate students or to a paid position, her husband became the head of MIT's mineralogy department, and his financial support allowed her to continue her work in an unpaid capacity.

Richards's research interests ranged from detecting chemical contaminants in the home, the food supply, and factories to evolution, microscopy, and women's education. In addition to designing curricula and teaching sanitary chemistry at MIT, she traveled to Europe, where she met Ernst Haeckel, who first proposed evolutionary theory to Charles Darwin. Richards so impressed Carl Zeiss that he later would donate microscopes and other instruments to her Women's Laboratory at MIT.

The Women's Laboratory was Richards's effort to allow women to study at MIT. With funds from the Women's Education Association (WEA), Richards opened a facility for women to study chemistry, biology, and finance. She also developed home courses for women through the Society to Encourage Studies at Home. Her efforts to see women admitted to regular degree programs were eventually successful. The Women's Laboratory closed in 1883 after MIT built a coeducational facility. In 1880 Richards founded the New England Kitchen of Boston, which supplied the poor with scientifically nutritious food that they could take home.

When her husband contracted typhoid fever in 1886, Richards conducted the first major analysis of Massachusetts's entire water supply and spent the next 27 years developing and teaching techniques in analyzing water, sewage, and air. She helped found the Seaside Laboratory for the study of ocean and inland waters, which later became the Marine Biological Laboratory at Woods Hole. In the 1890s, Richards began improving sanitation in the home environment, which she called "*oekology*" (Greek for "household study"). In 1893, she supervised the Rumford Kitchen, a model kitchen at the Chicago World's Fair. She also established the American Home Economics Association and the *Journal of Home Economics* to explore consumer aspects of science.

Richards continued her work at MIT until she died from a heart attack on March 30, 1911. In 1878, she was the first female faculty member at MIT and

became a full fellow of the American Association for the Advancement of Science. She was the first woman member of the American Institute of Mining and Mineralogical Engineers (1879) and the first woman to serve as the chief industrial chemist for Boston Mutual Manufacturers Fire Insurance (1883). Richards helped found the Association of Collegiate Alumni, now the American Association of University Women. As the "First Lady of American Science," she opened many doors for women.

Roebbling, Emily (1843–1903)

Though little known or celebrated, Emily Roebbling guided the Brooklyn Bridge project to completion when her husband could no longer do the job. Emily Roebbling took over the job in 1870 and saw the bridge, one of American's greatest architectural and engineering achievements, to completion in 1883.

Born in 1843 to Phoebe and Silvanus Warren, young Emily had a close relationship with her brother Gouverneur Warren. During the Civil War, Gouverneur commanded the Fifth U.S. Army Corps headquartered in Washington D.C. Emily visited her brother in 1864 and met Washington Roebbling. They married in 1865.

Washington Roebbling and his father, John Roebbling, were both civil engineers. John Roebbling was

Emily Roebling became the chief project manager for the Brooklyn Bridge, taking over for her husband in 1870, when he fell ill with decompression sickness. As the bridge's first field engineer, Roebling learned material strength, stress analysis, and cable construction to bring the bridge to completion in 1883. (The Picture Art Collection/Alamy Stock Photo)

also the man principally responsible for the design plans for a new bridge that would connect Manhattan and Brooklyn by spanning the East River. John Roebling, who had designed a number of suspension bridges before the Brooklyn Bridge, was injured when his foot was crushed between a ferry and a piling during a surveying expedition. Unable to continue the project, John Roebling handed the job to his son, Washington. John Roebling died in 1869 from tetanus contracted as a result of his accident. In 1870, Washington Roebling contracted what was at the time called

caisson disease, now known as decompression sickness or, more popularly, "the bends." Massive pine boxes, or caissons, were floated in the river and filled with stones to sink them to the bedrock under the river's bottom. These structures became the bridge's foundations. Many workers, including Washington Roebling, became sick from working on these underwater foundations. Washington Roebling's illness left him paralyzed, bedridden, and unable to continue the project.

At that juncture, his wife, Emily, stepped into the supervisory breach. At first, she served as a conduit between her husband and the crew at the construction site, carrying written messages back and forth between the two. Eventually her role expanded, and she became the project's unofficial chief civil engineer. To do this, she began to study civil engineering on her own. She mastered material strength, cable construction, and stress mechanics. She also managed all the paperwork for the bridge project, answered mail, paid the bills, and much more. Over the 14 years she acted as the chief engineer for the Brooklyn Bridge, she insisted her husband remain the engineer of record. In 1882, city officials determined to remove Washington Roebling as the engineer of record for the bridge project. Emily Roebling fought back, gathering testimony from a number of fellow engineers in support of keeping him on as chief engineer. In doing so, Roebling not only fulfilled current cultural notions of appropriate wifely behavior, but she also saved her own unofficial position as the bridge's actual engineer.

At the Brooklyn Bridge's completion ceremony, Washington Roebling was celebrated, but so too was his wife Emily. Indeed, Emily Roebling was in the first carriage to cross the bridge that day. After the bridge's completion, Emily Roebling moved to New Jersey and designed and built a mansion. She also worked for a number of woman-centered organizations, including Sorosis and the Daughters of the American Revolution. She often wrote and spoke about the inequalities facing women and advocated for increased female equality. She died in 1903. Her husband, Washington Roebling, died in 1926.

While it would be all too easy to dismiss Emily Roebling's contributions to the Brooklyn Bridge as no more than enthusiastic conduit between workers and

her husband, records make it clear that she was the bridge's real construction manager and engineer. Her insistence that her husband remain the engineer of record, while seemingly in line with contemporary notions of modest womanhood, probably contributed to her ability to keep her position as the real chief engineer. A plaque honoring all three Roeblings—John, Washington, and Emily—is affixed to the bridge today as testimony to the family's role in building one of the nation's great bridges.

Emily Warren married Washington Roebling in 1865. Washington took over construction of the Brooklyn Bridge after his father died of tetanus. Soon after, he became so sick that he could not leave his bed. Emily took over for her husband and in the process became the first woman field engineer in the United States. This stereographic card photo shows people walking

along the Promenade of the Brooklyn Bridge in 1899.

Roebling, John (1806–1869)

The civil engineer and designer of the Brooklyn Bridge, John Augustus Roebling, was born on June 12, 1806, in Mühlhausen, Prussia. Along with his

brother, he was an immigrant from Germany that came to United States in the early 1830s. The Roebling brothers founded a farming settlement called Saxonburg in western Pennsylvania. However, Roebling grew tired of farming due to his experience and

interest in engineering; he returned to a series of engineering jobs, including improving a canal system. During this era, boats traveling along canals were loaded onto railcars and were pulled across mountains using steel wire ropes. Because of this, on his Saxonburg farm, Roebling started producing his own wire ropes to use on canal systems. He adopted the method of twisting iron strands into a strong wire rope for durability. He also designed several suspension bridges and aqueducts using this wire rope, which quickly earned acclaims. By the late 1840s, he founded a successful bridge construction and iron wire rope business and moved to Trenton, New Jersey.

Roebling proposed the Brooklyn Bridge as a major civil engineering project during the late 1800s. The Brooklyn Bridge was a contemporary piece of architecture to the steel-arch bridge designed by James B. Eads over the Mississippi river at St. Louis, where it was the world's first major steel suspension bridge. The main parts holding the bridge together such as cables, suspenders, and the truss deck were all made of steel. The Brooklyn Bridge is still actively used and is estimated to carry an average of 145,000 vehicles per day.

When the bridge was constructed, its tower was the second-tallest piece of architecture in the whole of New York, standing at 276.5 feet. The main deck measured 85 feet wide and had a pair of rail tracks in the center for a passenger train between the regular lanes for pedestrians and coaches. It cost three to five cents for pedestrians and vehicles respectively to cross the bridge. Within a year of its completion, it was estimated that 37,000 people a day were using the Brooklyn Bridge to cross the East River and travel between Manhattan and Brooklyn. All the famous steel suspension bridges around the United States today, such as the Golden Gate and Tacoma Narrows Bridge all originated from this design, making Roebling the origin of all steel suspension bridges around the world.

When he started designing the Brooklyn Bridge in 1867, Roebling was already a respected engineer and successful businessperson. He claimed that steel was the “metal of the future” and proposed a plan for the Brooklyn Bridge in which all the suspension cables were made from steel. This was an innovative proposal, and it took the city and the federal government

two years to approve his design. Unfortunately, the same month that the design was approved, Roebling was involved in an accident on a visit to the construction site. His toes were caught and crushed between pier piles and beams by an incoming boat as it bumped against the dock. He then contracted a tetanus infection and seizures, dying 24 days after the incident.

Roebling's legacy lived on as his son, Washington Roebling, took over his late father's role as the chief engineer of the project when construction began in early 1870. Prior to this role, he had assisted his father on other suspension bridge projects and had the knowledge he needed to complete the bridge. Unfortunately, Washington was also faced with his own challenge when he contracted decompression sickness, then known as caisson disease, and he could no longer supervise the construction process. Fortunately for him, his wife, Emily, had assisted in supervising the project with a telescope from their residence. Emily Roebling also learned math and engineering from Washington and served as a communication liaison with the other engineers. Washington went on to serve as the chief engineer for the Brooklyn Bridge project for next 13 years, fulfilling the unfinished work of his father.

There are countless bridges around the world, but the Brooklyn Bridge is a monumental piece of architecture that represents the urban history of New York City. The great landmark has been standing strong since its completion in 1883, and pedestrians continue to visit the raised promenade. In 1964, the bridge was named as a National Historic Landmark. It is one of the major sightseeing spots of New York.

Roll Film

Roll film, also known as spool or cartridge film, is photographic film wound onto a spool. It replaced earlier glass-plate negatives and revolutionized photography by putting it within reach of the average consumer. Roll film standardized the size of photographs and gave birth to the snapshot.

Earlier photographic processes were cumbersome and dangerous. Glass plates coated with a light-sensitive emulsion served as negatives. They were heavy and fragile. Chemicals were also dangerous: the wet collodion process, introduced in 1851, utilized highly flammable nitrocellulose. Nevertheless, the process was popular because it created very detailed paper prints from glass negatives.

By the late 1870s, photographers were using dry plates coated with a gelatin containing silver bromide. The medium had a greater sensitivity to light, which allowed the photographer to dispense with a tripod. This led to the creation of smaller, lighter cameras that could be handheld.

George Eastman (1854–1932) and Henry A. Strong (1838–1919) capitalized on the new dry process, and in 1881, they formed a partnership and launched the Eastman Dry Plate Company. In 1884, the company name was changed to the Eastman Dry Plate and Film Company, and in 1889, it became the Eastman Kodak Company.

In 1883, Eastman announced roll film. His product consisted of a photographic emulsion coating on paper, which was then loaded in a holder. Eastman made the product available for all existing models of cameras. Eastman was intent on bringing photography within reach of the average consumer, and he focused on mass production to lower costs.

On September 4, 1888, Eastman received a patent for his new Kodak roll-film camera. The wooden camera sold for \$25 and held a roll of film good for 100 images, which needed to be returned to the company for film processing. The camera was heavily advertised with the slogan “You press the button, we do the rest.”

The compact camera was light and easy to use, making it attractive to both men and women. And there was no need to mess with caustic chemicals because the roll film could be conveniently processed. Eastman followed this success with the introduction of the inexpensive Brownie camera in 1900. It retailed for \$1 and used roll film that sold for only 15 cents.

In 1908, Kodak introduced a film that used cellulose acetate as a base layer, which was a safer alternative to the earlier, flammable film. The company introduced Kodachrome color transparency (slide) film in 1935 and Kodacolor negative film in 1942.

Roll film lost much of its market share in the latter part of the 20th century as digital cameras became widespread, but it is still in use by professionals and amateurs. In recent years, there has been a renewed interest in film photography.

Roller Coaster

Commonly found in amusement parks, roller coasters are generally elevated railroads featuring extreme ups and downs, including loops, tight turns, and even

inversions. Roller coaster cars are traditionally open, with riders strapped inside. Most roller coasters are of the “train type,” with multiple cars hooked together, though a minority use single cars. Roller coasters can be operated as complete circuits or as shuttle coasters, which begin in one location and end in another. Roller coasters are differentiated from scenic railway rides in that the latter ride sedately upon the ground, creating entertainment from the scenes the railway passes rather than the motion of the train cars.

LaMarcus A. Thomson (1848–1919) invented the first roller coaster. Known as the “Father of the Roller Coaster,” Thompson developed a number of “gravity rides,” or amusement park rides that used gravity power, rather than steam power as did traditional railroads of the time. Thompson’s first great roller coaster, the Gravity Pleasure Switchback Railway, debuted on Coney Island in 1884. In 1884, Thompson introduced the first scenic amusement railway ride at Coney Island in New York. The Thompson railway took riders past European landscape scenes and proved an immense success with amusement park goers looking for gentle entertainment. Hundreds of scenic railways opened in amusement parks across the country, the most famous of which is the Disneyland railway in Anaheim, California.

Ewin Prescott patented an improved roller coaster in 1899 that was the first to incorporate a loop into its design. Prescott’s patent letter describes a coaster with parallel tracks with steep gradients and circularly arranged loops. Cars were held to the track by centrifugal force (as were the people in the cars).

By the 1920s, amusement parks across the United States and the world featured roller coasters, from Coney Island’s iconic Cyclone, which opened in 1927, to the Giant Dipper on Santa Cruz, California’s boardwalk. Still in operation today, the Giant Dipper has seen over 60 million riders.

The so-called Golden Age of roller coasters and amusement parks ended with the advent of the Great Depression in 1929. The 1970s and 1980s saw a renaissance in amusement parks, pushed in part by a resurgence of interest in roller coasters. Modern roller coasters are made of steel rather than wood, allowing for greater sturdiness and reduced maintenance costs.

Despite the seeming dangers of roller coaster riding, the U.S. Consumer Product Safety Commission reports that they are relatively safe, particularly compared to some other recreational activities. A 2001 report established that two people were killed out of 319 million Six Flags amusement park roller coaster riders, showing that roller coasters are considerably safer than most sports as well as riding in an automobile.

Rotary Washing Machine

While other models of mechanical washing machines were appearing in other countries as well as the United States, Nathaniel Briggs invented the first mechanical washing machine in 1797—but that design was really no more than a washboard. James King patented the first drum machine in 1851, and though it resembled modern machines, it was hand powered. In 1858, Hamilton Smith invented a rudimentary rotary washing machine.

But it was Margaret Colvin of Michigan who introduced the first largely successful product, the Triumph Rotary Washer, in 1876, which took off after being exhibited at the 1876 World’s Fair in Philadelphia. Colvin’s husband initially marketed and made the machines, which were the most effective at the time because the “rotary” part of the machine involved rollers through which clothing would be fed in order to squeeze and extract the dirt.

While commercial laundries used steam-powered engines, home-use washing machines were either hand powered or run by single-cylinder, gasoline-powered engines until homes became electrified. Though the first electrically powered washing machine

was invented in 1880, they were not readily available until the 1930s.

Before the introduction of machines, the washer (generally a woman) had to scrub clothes on a washboard at a local river or hand-carry water to be heated on a fire in the home. Early machines simply provided hand-cranked rollers that moved clothing into a sink to be rinsed in clear water. Once rinsed, the clothes were fed manually back into the rotary rollers to remove excess water. The process to wash a “load of laundry” took an entire day, and this did not include drying and ironing the clothes.

From 1862 and 1894, 48 American women patented washing machines along with other items that contributed to the modern washing machine, such as wringers, drainers, and strainers. Around 2,000 patents had been given in the United States alone. By 1920, over 700 American companies were producing washing machines, such as Maytag, Bendix, and Whirlpool. These mostly appeared in upper-class homes or laundries for those of lesser income. It was not until the post–World War II period, when the GI Bill allowed for so many veterans to purchase homes in the newly created suburbs, that washing machines became a regular appliance in most homes. Even apartment buildings set aside areas for a laundry room to entice renters.

In the 21st century, washing machines require much less labor because they are nearly completely automatic. Oddly, household statistics suggest that women spend as much time doing laundry in the 21st century as they did a hundred years earlier. The reason lies in clothing cleanliness standards. The easier machines became to use, the more clothes Americans bought and the cleaner they had to be, thus belying the myth of the “modern convenience.”

Rowing Machine

Rowing machines simulate watercraft rowing. They are used both for training athletes in rowing events and for general physical fitness. William B. Curtis patented the first rowing machine in 1871.

Though simple rowing machines have existed for centuries, William B. Curtis patented an improved rowing machine that allowed the rower to practice through Chicago’s cold winters, when Lake Michigan’s surface froze. Curtis’s machine used a hydraulic damper design that improved rowing resistance. The design did not adequately mimic actual rowing, nor did it measure a user’s power generation in any manner. By 1900, rowing machines using pneumatic resistance had gained in popularity over the Curtis design, though they had the same weaknesses.

In the 1950s, Australian John Harrison built a friction brake machine that featured a large flywheel that allowed the rower to account for the weight and drag of a real boat. This rowing machine was the first to accurately measure the user’s power output and the rower’s range. In the 1970s, Norwegians made further improvements to the rowing machine.

Today, the rowing machine is used in home and public gyms. There are rowing machine competitions, culminating in the World Indoor Rowing Championships held in Boston each February. Computer and Internet technology have contributed to the popularity of rowing machine competitions, many of which are now online.

Saccharine

Saccharine, an artificial or nonnutritive sweetener, was discovered in 1879 by Johns Hopkins University chemist Constantin Fahlberg.

Fahlberg had hoped to discover a new food preservative using derivatives of coal tar. Widespread industrialization made this by-product of carbonized or gasified coal abundant, and similar organic compounds were already used for preservation and flavoring. After producing one apparently unremarkable batch, Fahlberg lifted a cigarette to his mouth and serendipitously tasted residue from the solution. He noted its extreme sweetness and took to calling it “saccharine,” meaning of or similar to sugar.

Fahlberg quickly grasped the commercial potential of his product. He continually refined and tirelessly promoted saccharine, attracting several large New York beverage makers by 1885. Fahlberg soon took saccharine international through a German industrial business syndicate, and together, they held a 15-year virtual monopoly over saccharine production and new coal tar derivation. This monopoly lasted until 1901, when John Francis Queeney, an independent sales agent with the German syndicate, established the first saccharine manufacturing plant in the United States. Queeney branded his company Monsanto Chemicals.

Fahlberg, the syndicate, and independent businessmen like Queeney marketed saccharine to food and beverage manufacturers over individual consumers. This wholesale strategy ensured exponential growth for Fahlberg and his partners, while manufacturers recognized the solubility of saccharine, its relative cheapness vis-à-vis sugar, and the volatility of sugar-producing states.

Significantly, even as saccharine was used in an increasing number of products, a few consumers registered the presence of the nonnutritive sweetener. This and similar issues proved divisive in an era of controversial additives; opium- and cocaine-ridden patent medicine, along with mislabeled foodstuffs, were cited as reason for passing the 1906 Pure Food and Drug Act. A classic piece of progressive-era legislation, the law essentially required truthful labeling by outlining criminal penalties for misbranding and adulteration. After the act, products made with saccharine had to be labeled as such.

Harvey Wiley, chief chemist of the U.S. Department of Agriculture, and his team of scientists had

been studying several food preservatives and their effects since 1902. Wiley compiled a list of adulterants, including saccharine, to be banned based on these trials. Yet, as historian Carolyn de la Peña has noted, adverse health effects were difficult to conclusively demonstrate in these potentially dubious studies. In any case, Wiley faced opposition from President Theodore Roosevelt, who enjoyed saccharine at the advice of his doctor. Physicians frequently recommended saccharine to alleviate ailments such as diabetes or, in Roosevelt’s case, obesity. The president appointed another panel to study the sweetener, which found that saccharine was not harmful in small amounts, but also that it contained no nutritional value.

This highly publicized ruling on saccharine gave beverage advertisers plentiful fodder. Companies attacked competing saccharine-laden products as unnatural, nauseating, and a swindle to boot. Sugar provided more calories per serving and was understood as an integral part of a balanced diet. Consumers largely rejected saccharine, even throughout the sugar rationing of World War I. By the late 1920s, saccharine purchases were generally limited to diabetics and the conscientious obese.

Saccharine became a household product during and after World War II. Rationing directed the majority of sugar output to men fighting overseas, as double dessert servings and seemingly limitless Coca-Cola in mess halls attested. Government propaganda asked women to forgo sugar carbohydrates for their husbands and sons’ nutrition. Many women answered this sacrifice with the use of saccharine. At that time, saccharine was typically available in pharmacy sections of stores. It came in tablet form, packaged in a pill bottle. Women often discreetly withdrew saccharine tablets from packaging when in public until manufacturers noticed surging demand and began marketing decorative containers and inconspicuous packets.

The expanding postwar economy had a similar effect on the postwar diet. At the same time, a growing body of nutrition science linked excess calories with poor health. Sugar had lost much appeal in kitchens following the Great Depression, wartime rationing, and the general stigma of excessive consumption.

By the late 1950s, full lines of products supplied saccharine where sugar was shunned. These included sodas, jellies, and even salad dressings. Consumers could also add granulated saccharine to items of their choosing with Sweet'n Low packets, which debuted in 1957.

The U.S. Food and Drug Administration (FDA) took interest in saccharine as it exploded in popularity. Studies throughout the 1950s and late 1960s were inconclusive, but in 1971, scientists revealed through animal experimentation a potential risk for bladder cancer. A 1977 trial by the Canadian Health Protection Branch confirmed these findings (though only in extreme circumstances), and in March of that year, the FDA announced its intention to ban saccharine on January 1, 1978.

This statement incited a consumer revolt. Hundreds of thousands of letters swiftly flooded the FDA and elected representatives. Writers mocked the results, which indicated that humans would have to drink the equivalent of over 800 diet sodas per day. Some advocated for individual choice, but most frequently shared stories of weight loss enabled by saccharine. This outpouring was organic, but the \$2 billion artificial sweetener lobby soon mobilized in defense of its product with full-page ads in nationwide papers. The FDA soon yielded to mounting political pressure and retreated from its stance on banning saccharine.

Saccharine sales remained ascendant until the early-to-mid-1980s, when aspartame, branded as NutraSweet, was introduced to grocery shelves nationwide. Profits dwindled, but Sweet'n Low and generic saccharine brands are still available in supermarkets. Americans continue to consume ever-proliferating brands of artificial sweeteners, including Equal, Splenda, and Truvia. Twenty-first-century nutrition researchers note that generations of artificial sweetener usage has not resulted in slimmer Americans. Some studies suggest that the human body metabolizes all sweeteners the same way, regardless of their caloric content, while bioethicists suggest that artificial sweeteners have not been sufficiently tested to determine their safety. Thus, the controversies about artificial sweeteners continue.

Silo

Fred Hatch is the American agricultural inventor of the towering, vertical silo that is often found in the Midwest beside a barn. Farm grain wasn't always stored in silos; it was stored in pits that farmers had to dig out, which caused excess spoilage in many instances.

Influenced by the grain storage pits and corn cellars of Native Americans, the first-known wooden tower silo was constructed in 1873 by Fred Hatch, who lived in McHenry County, Illinois. Hatch had just graduated from Illinois Industrial University, now known as the University of Illinois. At that time, there were few textbooks on agriculture. The only faculty member in the agriculture department at the university was Professor Willard Flagg Bliss, who improvised by translating foreign papers and other literature on similar topics. Hatch worked with Bliss in an effort to understand silo mechanics.

After college, in 1873, Hatch went back to his father's dairy farm in Spring Grove, Illinois. As a member of the Illinois second graduating class, he was eager to reveal what he'd learned at college. In the fall of that year, Hatch convinced his father, Lewis, to build a structure inside the barn to hold silage. He and his father dug a 10-foot x 16-foot rectangular hole that was 8 feet deep. They surfaced it with rocks, mimicking the way that basement walls were built in that period. The Hatches extended the walls above the surface another 16 feet, with multilayered flooring of two different thicknesses. The new design helped relieve rain spoilage and made the silo faster to fill, empty, and pack. It set the stage for another innovation with a separate roof on the silo. The silo would eventually be built outside of the barn.

That next fall, the men loaded the newly innovated silo with corn silage. Almost instantly, the cows stayed

heavier and delivered more milk than ever before. Until the 1870s, year-round dairy farming had hardly ever been an option due to harsh winters or because of the difficulty in providing sufficient moist feed for dairy cows to maintain milk production. But storing the silage in an airtight container stopped the fermentation process, preserving the feed until desirable, and most important, it helped create a boom in the dairy market.

Not remaining complacent, in 1876, the Hatches constructed two more silos, again indoors. Just like the original silo, they were identical in size; the only difference was that the subfloors were made of concrete instead of stone. Fred and his father knew they had an incredible innovation but never took advantage of the potential market. In that period, nearly 80 percent of Americans labored on farms and were in the need of this type of innovation, but farmers were slow to invest in this concept of crop preservation.

Years later, the use of silos spread by word of mouth and through several farming magazines. By 1924, there were more than 100,000 documented in the United States alone. During World War I, this was extremely important since farmers were being asked to generate more food to contribute to the war effort. Patriotic silo buildings alongside large barns were seen as a farmer's wealth.

The first upright silos were rectangular and often built of stone, sometimes limestone. They were expensive and often took months to build. They were not very tall. Even though their interior walls were two to three feet thick, they still could not resist the pressure of the kept silage. Though coated inside with cement, the silos cracked, allowing air to enter that would eventually ruin the silage. Cracks also allowed water to penetrate, and when it froze, it created more cracks. The corners of square silos also created many issues. In the 1890s, farmers began using round silos to solve this problem.

Through the years, silos have continued to evolve and have been built of wood, fieldstone, tile, brick, concrete, and steel. They have ranged in height from 35 to 60 feet. Beginning in the 1930s, barns and silos along state roads were sometimes used to advertise products or even annual events, grabbing attention and creating noise in the community like billboards in

today's era. With continued innovation, silos unfortunately also created a variety of other concerns besides the rotting of silage. Silage, as it ferments, produces many toxic gases, including nitrogen dioxide and carbon dioxide, which can be deadly if a silo is entered too soon after filling. There is also a newly found condition called "farmers lung," which is caused by molds in the top layers of silage. And when it freezes, silage sticks to the walls of a silo; there are many reports of farmers being injured by falling silage.

If it were not for Fred Hatch's work, farming might have been a completely different process today. His family's three silos were in continuous use until the late 1920s, when the farm changed ownership and the barn and silos were destroyed. However, in Spring Grove Park, a permanent marker remains memorializing Fred Hatch, the builder of America's first upright silo.

Skyscraper

Even today, the skyscraper is the icon of American business and a symbol of economic might. The skyscraper also represented a cultural revolution in office and real estate management. It offered a solution to the high cost of prime city real estate. For years, building height was limited by the strength of materials, insufficient water pressure, and the ability of people to climb steps to their offices. In the 1880s, buildings

over six stories were rare. Buildings carried their weight through the frames versus the internal skeletal structure. The Home Insurance Building in Chicago is recognized as the first skyscraper.

The Home Insurance Building was 10 stories high (138 feet). It was the first building to be supported on the outside and inside. It was also the first building to fully use steel frame technology. Skeletal support, not height, was the defining characteristic of the skyscraper. It was technically possible to build up to 10 stories with stone framing. The Flaxmill Building in Shrewsbury, England, was a cast-iron-framed building in 1797 that rose 11 stories. Six-story buildings became common with wrought iron beams and the invention of Elisha Otis's safety elevator in 1854. The Otis elevator had premiered at the Great Exhibition of 1851.

Cast-iron frames had become popular, but steel was needed for internal structures strong enough to carry the building's weight. Cast iron was popular because of its fireproof nature, since fire was a major threat to city buildings of the time. Stone and cast-iron beams had been used in the early 1800s, but true internal weight-bearing construction required the strength of steel. Wrought iron beams were an intermediate solution that Peter Cooper had pioneered in New York. Steel, however, offered the strongest material available. Steel has three to four times the tensile strength of cast iron. Steel was in very limited supply until the development of the Bessemer steel process in the 1860s; prior to 1870, Bessemer steel was not available in large enough quantities for building. Steel also had to prove itself, and that took place in bridge building. The demonstration of the load-carrying strength of steel would be the Eads Bridge in St. Louis in 1874. The 520-foot bridge was the brainchild of America's steel man Andrew Carnegie. Bridge designer James Eads had to convince Carnegie that steel could be used. Carnegie, however, had no steel mills at the time and had to purchase steel for his Keystone Bridge Company. The success of the Eads Bridge would usher in the age of structural steel for construction.

Carnegie would become a believer in steel, opening up his great Bessemer steel plant at Braddock, Pennsylvania, in 1875 and following it with his

massive, open-hearth structural mill at Homestead, Pennsylvania, in 1890. Carnegie would supply the structural beams for the building of the Brooklyn Bridge in the early 1880s. In 1883, it would be Carnegie who would sell steel to the Home Insurance Building architect, William Le Baron Jenney. Jenney had originally planned to use wrought iron beams and had actually started with wrought iron framing. Jenney actually built six stories before Carnegie convinced him to switch to steel beams. Jenney's use of steel framing won him the title of the "father of Chicago steel construction." The use of steel dropped the cost of insurance dramatically. The second steel frame building would come in 1886 with the building of Chicago's 12-story Rookery. Carnegie would build a 15-story skyscraper in Pittsburgh in 1890 using the "Chicago skeleton."
